Dr. B. FRANKLIN ROYER of Harrisburg said that in dispensary and sanatorium treatment some such follow-up system must be relied upon to prove the end-results that one aimed to attain. The following up of these more than 100,000 patients by nurses trained for the work to gather in an unbiased way the essential facts of health and of earning capacity, and then the efforts of the department to tabulate these facts into one mass so that they might be intelligently scrutinized by the students of the department, was the whole aim and object. The campaign of tuberculosis was almost wholly an educational one; the department aimed to teach the individual how he should live in order that nature might effect the cure. After all it was a question of food and open air, rest when needed, exercise when needed. It was a careful direction of the habits of life which resulted in the cure of the individual once infected, and it was a question of teaching that individual such methods of living that he would not infect the children who surrounded him, and it would take twenty-five to fifty years of just such an intensive educational drive in order to reach a point where their final statistics would show.

Dr. CHARLES H. MINER of Wilkes-Barre said that one part of the work in the dispensary was of special interest today, and that was to look up the soldiers who registered and who had been rejected by the draft boards and army camps for tuberculosis. At this time, of course, that was of greater importance than almost any other feature of the tuberculosis work of the department, because many of those men had never suspected that they had any trouble of that kind, and they especially should be sought out and urged to secure some advice and treatment. Many of them were very skeptical about having any trouble and were patients who needed the advice of the nurses and the physicians at the dispensary.

Dr. SCHAFFLE said they had received through the cooperation of Major Murdock, who was in charge, the names of over 1,200 draftees rejected by selective service boards throughout the State, and they wrote a letter to each man so rejected telling him that they had received confidential information that he had been rejected on account of tuberculosis and advising him to seek treatment through his family physician, or through a private institution if he could afford to do so; or, if not, through the department by means of its dispensaries and sanatoria. They followed that letter up by sending a dispensary nurse from the dispensary nearest the man's home to call upon him personally and to explain the matter at great length and to urge that he seek treatment because practically all of these cases are the early cases, cases who are curable. They had the same difficulty, however, that they had with the average incipient case. A great many of them refused to believe they had the disease.

Some General Considerations of the Ductless Glands in Military Practice.—Dr. CHARLES E. DE M. SAJOUS of Philadelphia said that, in summarizing all the facts, it could hardly be gainsaid that, insofar as recruits were concerned, proper recognition of the diseases of the ductless glands and their treatment would enable a large proportion of men, now deemed unfit, to continue their service. As for the armies in the field, it was a question of life and death in the large proportion of cases of disease of the adrenals or of the thyroid, including many cases of so-called "soldier's heart," as regarded the latter organ. All this should be taken to heart by our military authorities, if their excellent work in other directions was to encompass all fields of suffering.

Dr. JOHN A. LICHTY of Pittsburgh said that in considering the disturbances of internal secretion there were always two points which came out necessarily, and one of these was the early recognition of disturbance of function in typical cases, the other was the recognition of the aberrant cases. The treatment depended entirely upon the stage at which the case was met. In the thyroid or other glands of internal secretion, if a case was met at a time when the vegetative nervous system only was affected, surgery, or course, was not to be considered. These were the cases in which rest was the great factor. If the condition got to a certain point where neither of these two factors—rest, forced feeding, the administration of an internal secretion—were helpful—when it had gone beyond our control, we might say—then, of course, some direct effect upon the gland itself would have to be brought about and under those circumstances surgery would no doubt be called into play.

Dr. E. BOSWORTH MCCREADY of Pittsburgh stated that the reports of the army medical examiners showed how prevalent were organic and functional defects of development among the adult male population. Surveys of large groups of children had shown the existence of malnutrition to an almost incredible degree. It was to a large extent those malnourished, asthenic children who later developed the glandular anomalies under discussion. Food quality and food quantity were factors in metabolism, but only factors. Metabolism depended upon a proper balance of all physiological functions, particularly upon those of the ductless glandular apparatus. Preventive treatment should begin before the child was born, through proper parental care, including when indicated the administration of ductless glandular preparations to the mother, as had been for some time advocated by Dr. Sajous.

Dr. SAJOUS said that the influence of fright and excitement on the adrenals he thought was fully shown in this war, and it was one of the basic factors which brought about the terrible conditions sometimes witnessed. He thought if the surgeons in the army in general would but open their minds to that question they would find that in all hospitals at present cases that do not respond to the ordinary treatment of heart cases would immediately respond if they were cognizant of a knowledge of the ductless glands in connection with military medicine.

The Present Status of the Treatment of Syphilis.—Dr. JAY F. SCHAMBERG of Philadelphia said there were three recognized drugs in the treatment of syphilis—arsphenamine, mercury, and the iodides. Arsphenamine was generally recognized to be the remedy of paramount value. Its magical effect upon symptoms was due to the fact that it had a powerful destructive effect upon the spirochaete and that it might be administered in large dosage. Arsphenamine was fifty times less toxic for experimental animals than was mercury. Arsphenamine likewise had a roborant or tonic effect, which mercury did not possess. The spirochete was vulnerable to arsphenamine and to mercury. The iodides did not appear to have any direct destructive influence upon the spirochaete. In an attempt to eradicate every spirochete as early in the disease as possible, why should we not shoot with two arrows? He realized that Wechselman had warned against the use of mercury precedent to the use of arsphenamine, on

the grounds that in his belief most of the arsphenamine fatalities were due in large part to renal insufficiency, and that in the majority of cases it was mercury that damaged the kidneys. His belief was that the use of three inunctions of mercury per week was a valuable measure to associate with the use of arsphenamine, particularly in the primary and secondary stages of syphilis. No one was in an authoritative position today to state how long the treatment of syphilis should continue. Too often the physician will cease treatment after a single series of arsphenamine injections, and perhaps a course of mercury, because the Wassermann reaction has become negative. Experience proved that such a course usually required the later resumption of treatment, with valuable time lost. While it was difficult to prescribe any routine formula, we might at least indicate an irreducible minimum of treatment. Before any patient with syphilis was discharged from observation a diagnostic spinal puncture should be made.

Dr. Francis X. Dercum of Philadelphia stated that arsphenamine had been used extensively at the Jefferson Hospital, and he had used it in cases coming under his care in the exudative and in the form represented by tabes and paresis. His experience with regard to paresis had been that he had not infrequently remissions. Dr. Dercum was glad to hear Dr. Schamberg say he used inunctions every other day. In the old days they were used every day. He used with salvarsan half a drachm of mercury every other day and felt his way. He thought the drug was used too frequently. There ought to be an interval of ten days or two weeks. Very frequently he allowed an interval of two weeks.

A Method of Tracheotomy Without Loss of Blood.—Dr. Donald Guthrie of Sayre said he believed that the low operation of tracheotomy, unless there should be enlargement of the thyroid, was the more suitable for all cases—even the struggling child. If the patient was a child it was wrapped in a blanket or sheet to control its struggling and placed upon the operating table or on a table in the home. A pad of some sort was put under the shoulders and the head hung over the end of the table, steadied by an assistant. The operator stood on the right-hand side of the table and, steadying the skin with the left hand, made an incision in the midline of the neck 1½ to 1¾ inches long. The skin and the superficial fascia were incised and the wound held open by a pair of catspaw retractors which should not be more than 1 inch in breadth. When the deep cervical fascia was cut the parallel branches of the anterior jugular veins presented in the wound. The retractors were reset to pull these veins aside and the sterno-hyoid and sterno-thyroid muscles were separated by blunt dissection. If care could be exercised during this step of operation, the muscles could usually be separated without injury to the thyroid ima beneath. The retractors were again reset, the left blade holding aside the skin, the fascia, the two muscles, and the right blade the skin fascia, the muscles, and the thyroid ima vein. This exposed the trachea to view. It was incised, the head was straightened and the tracheotomy tube inserted. This method had been employed fourteen times in all types of cases by Dr. Guthrie and associates, twice in the home.

Dr. George P. Müller of Philadelphia said he thought he might first of all remark that it was gratifying that a surgeon of Dr. Guthrie's ability should turn from gallbladders and hysterectomies to discuss such a procedure as this. He felt, however, that he must, from his own thought and experience, mostly disagree with Dr. Guthrie's position. Those who were what might be called professional surgeons knew the exact anatomy of these structures. They were used to dealing with hemorrhage and hadn't the slightest fear of it. It didn't matter to a surgeon whether he did a high or low tracheotomy, but it seemed to Dr. Müller that it was by no means as easy for the general practitioner who had to do this operation to do the low as the high. When it came to operation in emergency in a patient with diphtheria or membranes, or other choking condition in the upper air passages, it seemed to him the high operation was preferable. Personally, he did the high. A low tracheotomy was dangerous if suppuration resulted, as it was liable to travel into the mediastinum.

SECTION ON SURGERY.

First Day, Tuesday, September 24.

Dr. John L. Atlee of Lancaster in the Chair.

Chairman's Address.—Dr. John L. Atlee of Lancaster said that all of our surgical principles and practices are being put to such a trial during this war as they never had been before, and only the absolute scientific truth could stand the test. In the past our progress had been hampered by the barnacles of sects and dogmas founded upon the most absurd theories, but scientific facts alone, not theories, could endure today. The absence of the great number of physicians who left their patients to serve their country would leave the door more widely open than ever to the charlatan and the patent medicine, and unquestionably this crisis was a wonderful opportunity for the quack. Let each and every one of us remember that we have every weapon that any charlatan, quack or patent medicine possesses, but that most of these weapons we should not deign to use; and we had one other which they did not possess, the knowledge of the science of medicine, and this was the one weapon no sect or system could withstand. At this time, therefore, above all others, we should study our art with diligence and apply it with careful thought and untiring energy.

An Anatomical Incision for Inguinal and Femoral Hernia.—Dr. J. Norman White of Scranton said in this paper that an incision 3 inches long, ¾ inch external to the spine of the pubes, commencing at and at right angles to Poupart's and extending toward the umbilicus, gave access at once to the inguinal canal and round ligament, and extension downward and slightly inward exposed the femoral ring. If a femoral had been mistaken for an inguinal hernia, or vice versa, no new incision was required nor extensive prolongation of the one already made. Infection was made less frequent and the wound never filled with fluid, as often happened with other incisions. This incision has the following advantages: No blood vessel need be tied because none were cut; it was a bloodless incision; the incision was parallel rather than across the blood and lymph vessels. Any operation in the inguinal region could be performed through one incision, including appendectomy. A common cause of infection was the catgut knot; in the anatomical incision there were no knots.

Dr. Harry C. Deaver of Philadelphia said that you could see by the incision that it was more constructive than destructive. It led away from the superficial epigastric vessels which ran on the line from Poupart's ligament to the umbilicus. Dr. Deaver stated that he had never tried Dr. White's incision, but it was an anatomical incision and any anatomical incision could not help but be a good incision, and he thought tomorrow when he operated he would try it.

Dr. T. Turner Thomas of Philadelphia said he had tried this incision in about a dozen cases. You did not get the same free and easy exposure of the canal as you did with the ordinary oblique incision. The novice would have trouble in locating the external oblique ring, but the experienced would not. So that was not an objection. He found that very few if any blood vessels were divided, and he thought that because the blood vessels were not divided that the healing ought to be a little better than with the ordinary incision. So that the effect on him of his little experience had been rather to incline toward the incision. He thought that there was enough advantage in the small number of blood vessels divided to warrant us in using it in spite of the little restriction in the exposure of the field.

Thoracic Surgery.—Dr. George P. Müller of Philadelphia said that thoracic surgery, and particularly that of the lung, had been affected to a considerable extent by the experiences of the war. While nothing very striking or very original had as yet been forthcoming, the invaluable point had been established that the lung may be handled, with proper technique, as freely as was the kidney or the stomach. Pierre Duval had shown us that the exposure of the lung and the removal from it of a foreign body was as safe as most other major operations, and not only enabled us to remove the bullet but also to clean the pleural cavity of its contained blood clot. Shortly after the receipt of the injury, when reaction had occurred, ether was admin-

istered by the open method (an endotracheal apparatus was not necessary) and an incision 9 or 10 inches long made over the fourth or fifth rib. About 6 inches of the rib was then removed, and after cutting the intercostal membranes the pleura was carefully separated with the fingers above and below for some distance to mobilize it. The pleural membrane was then rapidly divided the full length of the opening and a rib spreader rapidly placed in position and sprung open. The lung was then taken by a pair of grasping forceps and pulled to the wound. If these maneuvers were done rapidly the mediastinum was steadied before the pneumothorax had time to work injury to the circulation. The lung could then be drawn out onto the chest, the bullet easily felt, the lung incised over the bullet, which was removed, and the incision in the lung closed by one or two fine catgut sutures. Blood clots were scooped out, the cavity gently mopped and disinfected, if thought necessary, by ether (Duval) or perhaps Dakin's solution. The lung was then replaced, but still steadied by the grasping forceps, and the pleura closed. This was not so easy to do and it was probably impossible at times to avoid some tearing. The muscles were next pulled together with catgut mattress sutures and the skin sutured with silkworm gut. No drainage should be introduced. Finally, the pneumothorax was emptied by aspiration. If it was determined not to search for the bullet the pleural cavity was aspirated on the slightest suspicion of the onset of infection, and if cover slip smears confirmed suspicion the chest was opened and drained. The splendid studies of the Empyema Commission, published in the *Journal of the American Medical Association,* were accessible to everyone and should be carefully read for the many valuable technical hints they offered.

Dr. NATHAN W. GREEN of New York said that the question of operative procedure upon the thoracic viscera must be determined by the pathological or traumatic conditions found at the time. Injuries to the heart must be sutured. Injuries to the lung must be closed if possible, but if too extensive required a local resection of the injured area. Large vessels required ligation to control hemorrhage, but injuries to large vessels proved so rapidly fatal that they infrequently came to the operating table. In wide injuries of the chest the patient was in profound shock; of course then it was best to do as little as possible, and to wait until it had passed off. While waiting, septic infection might be implanted.

Dr. SAMUEL J. MELTZER of New York said that about eight years ago he constructed a simple apparatus for intratracheal insufflation for Dr. Carrel. He had seen in many of his experimental dogs, in which the thorax was transversely opened widely, double pneumothorax. These dogs recovered without having had infection. In the course of the last year Meltzer demonstrated to several hundred military officers anesthetized and curarized dogs with the chest wide open. The entire heart was exposed to full view. The animals were kept alive and with normal blood pressure by the method of pharyngeal insufflation. The experiment never failed. He had often demonstrated a fact of practical importance, namely, that if artificial respiration was sufficient the heart could be handled freely with impunity; but even a slight touch of the heart often led to fatal fibrillary contractions if the artificial respiration was suspended or was insufficiently executed. Artificial respiration was very useful during anesthesia, and was indispensable in major operations upon the thoracic cavity.

Absence of Clinical Symptoms During the Preperforative Stage of Duodenal Ulcer.—Dr. LEVI J. HAMMOND of Philadelphia said that of fourteen patients operated upon during the past two years at the Methodist Episcopal Hospital for perforated duodenal ulcers, not even the frequent complaint of digestive disorder was noted in the histories as occurring during their latent period. In none of them were such symptoms as paroxysmal pain, localized tenderness, vomiting, hematemesis, or hyperacidity of the gastric juices complained of. The patients were, with two exceptions, male, ranging in ages from fifteen to seventy years, the greatest number of them being between twenty and thirty. The two females were aged 22 and 26 respectively. None of the patients were chlorotic or anemic, and there was no history of burns or scalds or other serious accidents that could have been a factor. In most instances the perforations occurred while the patients were at their usual occupations. In one, perforation occurred during the middle of the night while the man was asleep in his bed.

Dr. FRANK ALLEMAN of Lancaster, Pa., said this series of cases of duodenal ulcer without preperforative symptoms seemed unusual. It seemed to him there must be some symptoms at some time in some of the cases. Dr. Alleman did not believe that the more chronic cases in which you have an ulcer with indurated edges are likely to have a perforation without symptoms.

Dr. MOSES BEHREND of Philadelphia said that it was his experience that many cases of perforation gave no symptoms. These cases usually occurred in men. They were working and suddenly were seized with terrific pain that overcame them, and perforation had occurred. On close questioning of these cases a history usually of gastric disturbance, commonly called "indigestion," was received, and it seemed to him that if the history were gone into more fully a gastric or duodenal disturbance would be found in many of these cases.

Dr. JOHN J. GILBRIDE of Philadelphia thought as Dr. Hammond's experience had shown, that it was not uncommon for us to have cases of perforation without any preperforative symptoms. Vomiting and hemoptysis are rare in duodenal ulcer. About the only symptom one could tie to would be pain. Hyperacidity was not at all diagnostic. Examination of the stool, that was the finding of occult blood, might be of value.

Dr. DONALD GUTHRIE of Sayre said that some 10 or 11 years ago when he was working as Dr. Graham's assistant in Rochester he became interested to see if just before perforation occurred there was any change in the classical state of symptoms. He was sent after the family of these patients and the patients themselves. He was very much surprised to find that several of the cases gave no previous history of duodenal ulcer whatever. The results were so confusing that nothing more was done with that problem. Since Dr. Guthrie had been in Sayre he had endeavored to find out whether there was any change in the symptoms during which the perforation occurred and the symptoms that all the patients complained of. He had been amazed to find that even by going after these patients and asking the most direct leading questions it was impossible to elicit any early ulcer history.

The Treatment of Malignant Disease by Combined Methods.—Dr. GEORGE E. PFAHLER of Philadelphia said that at least four methods had been proven to be of distinct and positive value in the treatment of malignant disease. Each method could claim many successes to its credit, but the profession and the laity knew well that each had also many failures. It was with the hope of influencing the profession to combine one or more of these methods in the treatment of malignant disease that this paper was read, for he believed that whenever additional help could be obtained from another method, or more than one, that the patient was entitled to this advantage. By certain skillful combinations he was sure that many cases which now were ultimate failures might have been made successes, and in this way advances have been made in the treatment of this dreadful disease. The four methods which stood out most prominently in his mind were surgical excision, electrocoagulation, roentgenotherapy and radium therapy. In every case in which the malignant disease was excised surgically, such excision should be followed as soon as possible by thorough roentgenotherapy, and sometimes radium therapy added. As the name electrocoagulation implied, there was produced a coagulation of the tissues by means of heat, the heat being generated by the electricity. It differed, however, from the thermocautery for the removal of the disease in that the heat was generated in the tissues and was produced by the resistance to the flow of the electricity through the tissues. Generally speaking, the effect of radium therapy was identical to that obtained by the Roentgen rays, providing that the two agents were used in equal amounts and equally well. The advantages of the Roentgen rays consist in the fact that one can apply approximately a million times as much radioactive effect in the same period of time,

granting that the case is suitable, and that the rays can be applied externally. The advantages of the radium, however, consisted in the ability to apply the radiation within cavities or in locations in which much energy would be lost in overlying tissues before reaching the diseased area. It also had the advantage of being applied with less technical skill.

Dr. G. Betton Massey of Philadelphia thought that the method that he had so many times presented to this Society, as long ago as 1897, in which a lower tension current was used than the current used by Dr. Pfahler, was particularly advantageous in the enlarged glands that were still movable in the neck. The reason was that one could handle both electrodes. In the high frequency current one was using thousands of volts in order to get two amperes of current, and could not bring the electrodes together because of the sparking. Dr. Massey found the most successful removal of these glands to be not to incise the skin, but after the destruction of the primary growth in the mouth or lip to pick up the gland with its overlying skin and pass a loop of thread beneath it by which it was pulled away from the blood vessels. With several zinc points then passed beneath the gland and the opposite pole held on the skin over the gland, a current of half an ampere to an ampere was turned on and the gland cooked or destroyed entirely in ten or fifteen seconds.

Some of the Postoperative Sequelæ of Acute Appendicitis.—Dr. John B. Deaver of Philadelphia said that in 1700 operations for acute appendicitis collected from recent records at the Lankenau Hospital of Philadelphia, 66 deaths gave a mortality of 3.7 per cent. The series included all cases of acute appendicitis with and without preoperative complications directly due to the condition of the appendix or to the involvement of other viscera. Of the complications, fecal fistula occurred in 42 cases, secondary in 30 and intestinal obstruction in 27 cases. An analysis of the cases of obstruction showed that fully 70 per cent. required drainage at the original operation. There was no doubt that every case of acute appendicitis requiring drainage had been safely taken as an indication that operation was delayed beyond the most favorable moment. In the prevention of surgical complications there was nothing more important than to forestall the formation of pus within the peritoneal cavity. A large number of these cases would not have developed adhesions and consequent obstruction if the original appendicular disease had been treated early and no drainage had been required. In practically every case of death from appendicitis someone was to blame. The question was who was at fault. Was it the wise and experienced parent or guardian or friend who refuses to consent to, or advises against operation because he has had his appendicitis frozen out, or was it the ill-advised administration of an aperient or purge, or was it the doctor? It was too often the latter he was sorry to say. Summing up the facts undoubtedly showed that purgation was the primary cause of the complications he had been discussing and late operation the main contributing factor.

Dr. H. J. Donaldson of Williamsport said that Dr. Deaver had mentioned as post-operative sequelæ fecal fistula, secondary abscess and obstruction, and to these he desired to add acute renal insufficiency, acute gastric dilatation and hemorrhage from erosion by drainage tubes. Of the fecal fistula group his experience led him to believe that the causes were gangrene of the base of the appendix involving some area of the cecum, failure to remove the appendix, erosion of the intestines by the drain, and ulcer of cecum due to thrombosis of the blood supply, or extension of gangrenous process. To overcome this embarrassing occurrence, it had been his habit of recent years to always remove the appendix, to sufficiently free the adhesions, to admit of invagination of cecal wall if gangrenous, and to effect an early change in the position of his drainage to prevent pressure upon the bowel or large blood vessels and other important structures. One of the greatest lessons he ever had in drainage tube accidents was a sudden death of a man rapidly recovering from a general peritonitis, who on the seventh day developed a hemorrhage from his iliac artery and died in a few minutes.

Radiographic Diagnosis of Ileocecal Valve Incompetency.—Dr. Mulford K. Fisher of Philadelphia said that it was only within comparatively recent times that ileocecal valve incompetency had been recognized as a distinctly pathological entity. Without x-ray study it was impossible to diagnose the condition clinically. As a result of over-stretching, relaxation and weakening of the walls of the bowel, the valvular function disappeared, even with destruction and final disappearance of the valves themselves; there was widening of the lumen with easy passage without hindrance to the passage of the intestinal contents, and finally with atony and stasis established, return in the reverse direction from the large into the small intestine was easy of accomplishment. From a radiographic viewpoint, the diagnosis of incompetency does not present much difficulty. Ileocecal valve incompetency was such a frequently overlooked condition, was so readily roentgenologically diagnosable and cure so readily effected by a simple surgical procedure, that persistent reiterations of its importance should be made so as to focus and retain the interest of the profession on what was a distinctly pathological problem.

Dr. Thompson Schell of Philadelphia said that for over three years now he had been plicating the dilated cecums and ascending colons after removing the appendix and correcting any kinks caused by adhesions, and with very much more satisfactory terminal results. About two years ago his attention was drawn by Dr. Fisher to the work Kellog was doing with the ileocecal valve incompetency, and he was favorably impressed at once, as the failure of this valve to properly close would account for many of the failures noted in the past, and would also explain the much more satisfactory results following plication of the cecum, for in plicating the cecum the ileocecal valve to a certain extent had been improved, although Dr. Schell had not realized this at the time.

Second Day—Wednesday, September 25.

A Modification of the Technique in the Watkins Interposition Operation, Designed to Permit Future Childbearing Without Complications.—Dr. John Cooke Hirst of Philadelphia stated that his experience with this operation extended over a period of 4½ years and comprised a total of, up to the present, 141 cases. Not all these cases were of childbearing age, though the majority were, but the same technique was used in all of them. He had seen no primary failures, and none of the cases had required a second operation, as far as he knew. Certainly none had returned to him. The results as to subsequent delivery, excluding cases done within the last year, which were too recent for definite statements, were as follows: Of 89 cases, the history of 49 was known. The others he had lost track of. Of the 49 known, 7 had become pregnant. Of the 7, 2 miscarried, due probably to over-exertion, of which there was a definite history in each case. Five went through labor at term, one of them twice. Four of the 5, including the one with two deliveries, showed a very normal looking anterior vaginal wall, the surgical result was good, and they were symptomatically well. The fifth case had a measure of recurrence. The anterior wall sagged considerably, but nothing like the extent of the previous cystocele, but the patient was symptomatically well and insisted she required no treatment. Whether the cystocele would increase in size it was as yet too early to determine. It seemed to be stationary up to the present.

Dr. M. Behrend of Philadelphia said that there was no question as to the value of Dr. Hirst's operation. The immediate result was perfect, and it was encouraging that for these prolapses in early married life or in single girls it was an ideal operation.

Aseptic Technique in Obstetrics.—Dr. Charles G. Strickland of Erie said that in his home city there were in 1917 2590 births with 7 deaths from sepsis reported, or about 0.3 per cent. Dr. Strickland said he had been disturbed at the frequency of puerperal sepsis in our city hospitals. The condition was admittedly a wound infection, and implied, except in rare instances, the direct introduction into wounds of infecting microorganisms foreign to the victim. Together with our lack of perfect asepsis we have two other great faults which contribute to puerperal morbidity, that is, over-frequent vaginal examinations and

undue operative interference. Unindicated operative interference, whether it be the application of forceps or undue haste in manually removing the placenta adds a distinct risk. He felt that a certain amount of discretion should be used with the immediate repair. If the patient had been fatigued from a protracted or complicated labor, it was wiser to wait than to repair at once. Fatigue, toxemia, or hemorrhage must lessen individual resistance to infection, and the chances were that the long or complicated delivery had impaired the doctor's asepsis as well.

Dr. ALFRED HEINEBERG of Philadelphia said that the essayist had presented a very timely subject for consideration. In these days when it has become a custom for women to seek hospital treatment for confinement, it should be the aim of those hospitals which admit cases of that kind to eliminate as much as possible the chances of infection. The development of an aseptic technique in obstetrics in hospitals should not be any more difficult than the development of an aseptic technique for other operative procedures. The difficulty resides not so much in the establishment of the technique but in commanding adherence to its regulations. Hospitals should provide a delivery room separate from the operating rooms, and it should have as the essayist contends as careful supervision by the nursing staff as the operating rooms. The ideal measure which had been adopted by many hospitals was to have the obstetric department in a building separated from the main building, so that neither the nurses nor the patients were likely to come in contact with sources of infection from the other departments of the hospital.

Third Day—Thursday, September 26.

The Foot of the American Soldier and Its Care.—Lt. Col. J. T. RUGH of Philadelphia said that it was early recognized that the conditions met with in the army were at total variance with those in civil life, and while a foot with potential weakness might prove equal to civic demands, it would fail utterly under military use. Drill and work kept a soldier on his feet for from 8 to 12 hours a day, and usually he carried a pack or gun, or both, during this work. His play was intensive and every move of the training process was designed to eliminate the weak spots and parts. Whether this obtained through the strengthening of the part to a point equal to the demands or by breaking it down, depended upon the fiber of the man himself. The province for us, as physicians, was to anticipate this result and spread the propaganda for better and more sanitary foot-wear. We should teach our patients and our community the essentials of foot health; counteract the malevolent idea that prevailed of the high heel and pointed toe shoe which cramped the feet, altered weight-bearing proportions, and compelled function in an abnormal position and manner; it was taking the costume of the drawing-room, reception and ballroom out onto the street. That type of shoe was never designed for work, and the warped mental attitude which compelled so many people to use it wrongly must be changed by a healthy sentiment based upon everyday knowledge of physiology and anatomy, and now verified beyond question by our vast war experience.

Bone and Joint Casualties and the Transport Splints.—Lieut. Colonel ROBERT B. OSGOOD of Boston said that in any serious engagement we might expect nearly one-half of the severe injuries to involve the bones and joints, and among these the phenomenon of shock was very common. They become, therefore, of great importance, and the problem of their transport from the battlefield to the Evacuation Hospital where they receive their first thorough surgical overhauling demanded energy and wisdom in its solution. Shock was of first concern, and infection was a close second. Perhaps the most common cause of shock was trauma. Infection fed first on traumatized tissue. Transport must always add trauma to trauma already existing. It became the first duty of the surgeon to lessen this trauma by every possible means. Proper splinting materially lessened it; therefore, proper splinting became of first concern. The first essential in good splinting for transport was the comfort of the wounded man. If the splint gave him ease from his wound pain and did not add another discomfort, the first requisite was met. The splints must also fulfil the mechanical purpose for which they were applied. The design of the splints must be simple and their weight light, in order that they might be manufactured in large quantities and be easily transported far up the line to the battalion aid posts. For fractures of the long bones and certain joint injuries it was extremely desirable that they should embody the two principles of fixation and traction: fixation, to protect the injured structures and to retain proper alignment after the alignment had been secured; traction, to bring about muscular relaxation with the object of diminishing pain by inhibiting voluntary contraction, which also resulted in malposition.

The Care of the Amputated in War.—Lt. Col. DAVID SILVER of Pittsburgh said that loss of limb was one of the most disastrous of the ravages of war. The care of the amputated had always been a serious problem during a campaign, and in a war of any magnitude an economic factor of importance afterward. Surpassing as it did in every aspect all other wars, this world war was expected to present unusual demands for the care of the amputated. To the injuries caused by shot and shell had been added the destructive results of gas gangrene and trench foot, so that in the early years of the war amputation was unusually frequent. More recently the prevention of trench foot and the better understanding of gas gangrene had resulted in a very great saving in the number of amputations from these causes. Yet this had probably not produced a corresponding decrease in the total, since with the improved methods now practised in the care of the wounded it was reasonable to expect a considerable saving of life in the more severe cases requiring amputation. It seemed likely, therefore, from present indications, that this type of injury would constitute a very large proportion of our permanently disabled.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

ON THE FRINGE OF THE GREAT FIGHT. By Colonel GEORGE G. NASMITH, C.M.G. 263 pages. Illustrated. Price, $1.50. Published by George H. Doran Company, New York.

PRACTICAL BACTERIOLOGY, BLOOD WORK, PARASITOLOGY By E. R. STITT, A.B., Ph.G., M.D. Fifth Edition, Revised. 559 pages. Illustrated. Price, $2.00. Published by P. Blakiston's Son & Co., Philadelphia.

THE EVOLUTION OF NATIONAL SYSTEMS OF VOCATIONAL REEDUCATION FOR DISABLED SOLDIERS AND SAILORS. By DOUGLAS C. MCMURTRIE. 319 pages. Illustrated. Published by Government Printing Office, Washington. Bulletin No. 15. May, 1918.

PROGRESSIVE MEDICINE. Edited by HOBART AMORY HARE, M.D. Assisted by LEIGHTON F. APPLEMAN, M.D. September 1, 1918, issue. 287 pages. Illustrated. Price, $6.00 per annum. Published by Lea & Febiger, Philadelphia and New York.

GYMNASTIC TREATMENT FOR JOINT AND MUSCLE DISABILITIES. By Brevet Col. H. E. DEANE, R. A. M. C. 146 pages. Illustrated. Price, $2.50. Published by Oxford University Press, American Branch, New York.

CASE STUDIES IN MENTAL DEFECT. Eugenics and Social Welfare Bulletin, No. XIV. 177 pages. Published by the New York State Board of Charities, Albany, N. Y.

THE ACTION OF MUSCLES By WILLIAM COLIN MACKENZIE. 267 pages. Illustrated. Price, $3.00. Published by Paul B. Hoeber, New York.

GLAUCOMA. By ROBERT HENRY ELLIOT. 546 pages. Illustrated. Price, $7.50. Published by Paul B. Hoeber, New York.

GENITOURINARY DISEASES AND SYPHILIS. By HENRY H. MORTON, M.D., F.A.C.S. 807 pages. Illustrated. Price, $7.00. Published by C. V. Mosby Company, St. Louis.

THE PSYCHONEUROSES OF THE WAR.

AN ANALYTICAL AND CRITICAL SURVEY COMPRISING INTERPRETATIONS OF EXHIBITED PHENOMENA UPON BASES, BIOLOGICAL, PHYSIOLOGICAL AND PATHOLOGICAL, WITH DIAGNOSTIC HINTS AND THERAPEUTIC SUGGESTIONS.

By HOMER WAKEFIELD, M.D.,

NEW YORK.

In our two previous articles we have discussed the pathogenic reactions of volumetric anemia caused by serious deflections of the blood, which produce superficial and extremity capillary evacuations, and as the effects of same, of deep venous engorgements and stases. We have pointed out the exaggerated reaction of hyperesthesia and the excessive recoil-producing factors of war as productive of blood deflection, anemias, and asphyxias of the periphery and extremities primarily, and of anesthesia secondarily, as obvious sequence resultants.

We have directly connected up the fundamental biological factors of density of living substance, with the typical reaction characters on the one hand and with the so-called neurotic characteristics, hyperesthesia, and anesthesia, on the other. We have thus lifted from the domain of vagary and superstition the several typical features of hysteria and other psychoneuroses and set them firmly within the field of biophysiological progress.

We now have remaining for analysis and elucidation some conditions especially related to the war psychoneuroses, to which we will devote the text of the present paper. Other applications of these etiologic factors must go over to subsequent considerations.

Abulias, Amnesias, and Other Diseases of the Will, and of Motor Acts.—A characteristic feature of the mentality of hysteria in which anesthesia, abeyance of memory, and retraction of the field or scope of consciousness are no less typical features, is a corresponding failure to mature, to give definition orientation, and specific form to a motor sequence of the sensory preamble. The mechanism may be stalled by a primary break in continuity, a failure of development, of organization and forms of specific acts. A will to do fails in its very inception, exemplifying the well recognized abulias. Other cases are characterized by feeble efforts soon abandoned. Others still exhibit endeavors which are defeated by tetanic shambles, quivers, flutters and tremors (stammering and stuttering come in this category). Yet others exhibit somatic frustrations of voluntary movements of a type which we have already discussed as *Flustrations*, what the French term *commotional confusion* and other war authors call *concussional confusion* 37, I.

The Charcot School recognized abulias as manifestations of failure of the will, and amnesia as a failure of power to do, rather than to will. The difference is slight, but it appears that they are both diseases of the will, though desire is aroused in amnesia and little if any in an abulia. In amnesia the memory is partially or completely in abeyance. Sidis[25] describes an American case of complete loss of memory with considerable detail. It was a case of traumatic amnesia.

Hysteria is primarily a disorder of the volition, even when the major events are not in evidence, the lesser one of abulia exhibits a failure of development to maturity of that synthetic product which is most intimately related with the individualistic character of the ego, namely, the will. Janet[18] observes: "All hysterical stigmata depend on a psychological insufficiency, which manifests itself by disturbances of attention and will, by absent-mindedness, continuous amnesia, etc." This conclusion ignores the fact that the attention is a tensional state of necessary physical senses, and that the absent-mindedness and the exhibitions of will disturbances are functions of the body, the abeyance of a function of which he himself furnishes evidence.

Sensory reception and tissue response as a mind reaction constitute the preamble of every mental and motor act. Every elaborated mental function and its motor and other expressions or volition, hark back, not merely to the phase of elaboration, but to the primary physical response phenomena which we term sensation. When its prime importance is ignored the after hypothesis is apt to be false. It cannot be scientifically arrived at.

Incoordination and discoordination alike exhibit incongruities and incompatabilities between two heterogeneous factors. The attained heterogeneity may be of reaction time, velocity, etc. Examination discloses the presence of both of these factors. There are also heterogeneities of esthesia, of contraction and relaxation. Confusion and chaos reign where disequilibrium and unbalance are thus enforced by unequal deviations from the normal. Mental balance involves coincidence in their cooperation.

Let us for a moment permit our imagination to follow an ordinary reaction of contractile tissue (all tissues differing in degree of contractibility only. Even tendons exhibit reflexes or recoils). During periods of hyperesthesia, a sensory precocity occurs and the intensity and velocity of primary reactions are greatly accelerated, while the memory element, essential to the elaboration of the same sense insti-

gated reactions, is delayed in inverse ratio to the acceleration of the preamble. Thus the sensorial reaction occurs unelaborated by the individual's past experience.

Let us observe that the subconsciousness finds outer expression during somnambulism, general hypnosis, ecstacy, hysterical paraplegia and hemiplegia automatic writing through an anesthetic arm, etc. All of these states are anesthetic. If but one arm is anesthetic, that arm only is capable of automatic writing. Now, it is *volition* which is paralyzed by anesthetics. It is the senses connected with volition that are anesthetized. The patient is left free to somnambulistic wanderings, to automatic writing, etc., in which the subconsciousness finds expression. It is when the *voluntary* muscular system is in abeyance during hypnosis that the expression of the subconscious group is artificially given expression. During dream states the voluntary muscle group is in abeyance, and with its disappearance a disease affecting volition such as amnesia, is exhibited. It appears that normal consciousness and volition are indivisibly associated. They constitute an ego by themselves: The *I* and the *I do*.

Suggestibility and Distractibility.—A combination of weakness or lack of tenacity of thought continuity, together with a hyperesthesia of sense perception and of mental imagery predisposes to both suggestibility and distractibility. It is the overt facility of departure from continuity of subject which is incited by hypnotic suggestions and by current distractions that render normal thought continuously impossible, and at the same time practically facilitates desultoriness and fugitiveness of thought.

In the hysterical state the hyperacuity of sensation, combined with a blunted or anesthetic memory element, insures a state of disequilibrium of mental elements that predestines a complete reaction to the sense impression which is little if any modified by the memory element. Such a state of mental function characterizes the typical state of suggestibility of hysteria. The slightest additional suggestional impetus further activates the already hyperesthetic impressionability as directed by the uttered suggestion and simultaneously completely silences all memory interrelations, leaving the suggestion as a complete substitute for the memory element then in abeyance. All foreign and modifying factors of thought are excluded by the spasmodic cleavage of the sensorial element.

In cases where a serious circulatory disequilibrium obtains, when hypnotism is exclusively employed remedially, it must attain a readjustment of the disequilibrium. Where this fails other more efficacious means must be utilized to accomplish that end. Specific suggestions of warmth of body surfaces and of the ext remities greatly facilitate its accomplishment. They are much more successful than merely belittling or denying the existence of the disorder (Eddyism fashion). Slow passing of the hands over and toward the extremities, from points above any anesthetic area, accompanied by appropriate suggestion, is more apt to extend the area of sensibility and other vital attributes than without it. The addition of strenuous, even painful, manipulation is, however, yet more efficacious. The fact is that but a fraction of American soldiers are amenable to hypnotism, a much smaller number than of the French, yet in selected cases the recoveries are frequent and rapid.

Suggestibility demands a certain degree of hyperesthesia, a spasmodic effect must be produced to attain a definite recoil or shock like reaction. It is the effect of this same spasmodic reaction which restricts the ensemble of consciousness and makes way for that of the subconsciousness to attain dominance and expression. Suggestions may be defined as dissemblers of the conscious concert, as desystematizers and as disrupters of conscious unity. With that attained we have two personalities or egos, one of which is reached by *subconscious* and the other by *conscious* avenues.

Fixed ideas are defined as persistent subconscious suggestions which are generally associated with hyperesthesias, which would suggest their tetanic character. These persistent *unconscious* memories carry the details of many accidents and experiences of traumatic shock, of which the *full consciousness* is oblivious. To cure them, that cause must be eradicated.

Religious psychologists point out the remarkable effect and of subconscious suggestion of the oft repeated spoken words in religious songs, especially those of rhythmic sway and of marked dynamic force and velocity, as unconsciously impressing undeliberated religious dogma upon the unwary. This has analogy in many instances wherein the subconscious mind receives impressions which do not attain the fully conscious attention.

Crowd or mass hypnotism is greatly facilitated by a series of shocks, such as reproof, rebukes, reproach by sharp reprimands, and brutal invectives. Religious psychologists tell us that it is made use of by a certain type of evangelists. Some have added the shock effect of punctuating sentences by raising the heels and bringing them down with considerable force. Each concussive impact is attended with a shock effect, a recoil, a revulsion, which act collectively as a progressive series of distinct perturbations. Bernheim says: *all belief is suggestion.* Jastrow" says that the original source of *conviction* is emotion. Both indicate the shock or spasm genesis of the fixed idea. Especially during the impressionable and suggestible stage of war shocks it is important that the "atmosphere" and all indirect and passive suggestion should be cheerful and optimistic, and beyond that they should be step by step for specific ends, rather than general.

The Seat of the Mental Mechanism.—It is inconceivable to us that the organ of mind is limited to the brain. If one traces the simpler mental processes, beginning with sensation and ending with muscular acts of will, the brain is found involved simply as an organ of intercommunication and relay battery which we believe it to be. Yet its functions are no less important or vital.

If, for example, the sense of touch, a burned finger, be the source of extraneous perturbation, the original reaction is the recoil of the living substance or protoplasm *at the point of injury.* This reaction is communicated over the sense nerves to the brain, whence it is interacted with such kindred and associated memories as are reverberated by its harmonious impress. A direct reaction takes place be-

fore these intercommunicating reactions can be accomplished, which we term *reflex action*, which jerks the finger from the source of heat, before—as we say—we have time to think, but the finished mental picture, the essence of the interaction constitutes the engendered thought, that which we term the experience, and upon which depends our deliberated acts in regard to it.

Within the brain the complexity of the mental act is accomplished by the interaction of the elementary units of the composite whole which we term consciousness. There they communicate and intercourse in every conceivable relation and are influenced by avidities and repulsions of hetero- and homogenity. The brain is truly the seat of intercommunication of the nervous fibers from and to the whole body, but to say that it is the exclusive seat of thought is exceeding the facts in the case.

To those unacquainted with physiological psychology and its physical and material bases, the gulf between the highest expressions of human intellect and the lowest of animal and vegetable forms of life, appears so wide and unbridgeable that it is hardly conceivable how they can be analagous. When, however, we consider that the highest faculty of human mentality is the power of differentiation and discrimination, we can appreciate the close relationship with the lowest organisms, all of which possess this faculty in some degree. It may be said that the mind of man differs in *degree* only, and not in *kind*, from that of the lower animals. The lesser mental elements of man are observed among those exhibited by animals of all degrees in the zoologic scale. All orientation and specificy of definition involves discrimination.

Primitive human concepts of mentality—as of some obscure outside force—acting as an entity, on and through the human body, from a particular point of action, and of the soul of man as the real individual spirit seated in the heart, the pineal or pituitary gland, or the brain at large, and from these acting in the material body, exerts no small influence in those insidious psychological notions, still prevalent, which are termed *intuitions*. Some empirical psychical theorists entertain such views.

It is a singular fact that large numbers of more or less scientific individuals, whose matured consciousness is wholly and scientifically based on materialistic and solid foundations, have stowed away in their *subconsciousness* a "still small voice" which has a spiritual, a metaphysical or entirely mystical interpretation of the same phenomena. The old saying, *a Jew is a Jew, a Catholic is a Catholic, at heart*, has reference to the same subconscious elements, which though anesthetic to the mature consciousness, nevertheless expresses an insidious influence upon *conscious* thoughts and acts, which may, by education and training, entertain contrary views when they are fully conscious. Such is the case with many individuals who entertain all manner of strange views in their subconsciousness which are not permitted a place in conscious thought, but find expression in dreams, reveries, deliriums, and in moribund states.

Natural Selection in Psychology.—We have considerable evidence to substantiate the theory that the law of natural selection is exhibited in mental, as well as purely physical phenomena. It appears that our facility of assimilating and retaining sense impressions depends upon their utilization, and conversely, that we exhibit a sort of disuse atrophy of impressions of anti-utilitarian value. Among such may be named those sensibilities which originally keen and alert in primitive man have fallen into disuse in present states of civilization. The olfactory sense, in particular, is an example.

There are many instances of lost perception avidity on the part of modern man for continually occurring sense impressions, of which he has not present need and that fail to attain the cognition of the conscious mind. They therefore find haven only in subconscious ensembles. In this capacity, however, they do ultimately exert certain unperceived influences upon the conscious mind or waking state, and under certain conditions, on occasions of great emergency attended by shock recoils, as of fright, of strong emotion, or of hysterical states of somnambulism, delirium, fixed ideas, automatism, etc., the higher consciousness is disrupted by exclusion of its usual memory element, and its place is taken by the *subconscious* substitute, thus forming a new ego (for it is the memory that constitutes the ego), unknown to the other ego of the memory group of full consciousness. Thus we observe double personality as a resultant of shell shock. The problem of why it is that when hysterical disruption of psychic unity occurs, the memory factor of the normal full consciousness is effaced and the remaining subconscious group continues and entire into outward physical expression, is one of great biologic as well as psychologic interest.

If we tentatively accept the hypothesis that all memory consists of repetitions of original reactions, and that each repetition involves the same tissue group that reacted to the original subjects of memory (not excluding any involved sense organ, the cutaneous surfaces and motor organs, as well as the intercommunicating nervous system), we are in position to understand that different tissue areas are involved in the daily life groups of *full consciousness*, than are involved in the usual unelaborated and unusual ones of *subconsciousness*. Many of what are known as instincts, many of which are hereditary, but seldom find utilization in our present artificial life, seem to be relegated to the subconscious group, and when that group holds sway the individual appears more independent of reason than when in possession of full consciousness. The more rudimentary tissues of lower density are typically those predisposed, first to hyperesthesia, and then to anesthesia. Does the hysterical effacement or abeyance of the memory elements of full consciousness amount to a reversion to an atavistic condition? Is it not a subconscious group that is operative during infancy while we are acquiring our conscious group by daily experience, one that is later to gain the ascendancy and dominate the conscious reason and will?

Subconscious reactions and expressions emanate from more or less benumbed and anesthetic tissues, the *conscious* proceed from the sensitive. The subconscious state is manifested by three most significant features: the abeyance of the memory factor, which is dependent upon certain anesthesias as a second factor, and upon a retracted field of consciousness, as a third factor. In other words, some

one or more constituents of the mental ensemble or field of consciousness are functionally in abeyance. The circumstantial evidence points to *anesthesia* as the present and exhibited cause. The missing element from an otherwise full concert of the elements of consciousness is that of *memory*, and of those *voluntary* acts that are dependent upon it.

The essence of volition is the ego. Voluntary action proceeds from the self. The memory provides this feature of self identity. The self is the life history of the individual. When the memory is obliterated, as in amnesia, all specific relationships and self identity are gone. The composite, the complex individual experience is the personal unit of identity which we term the ego. When animal activities lose the conscious state of attention in the light of the identity relation of its past experience, we characterize them as unvolitional or involuntary. The conscious element of that attention is the resultant of elaboration of the *sensory* preamble by and with the *memory* element, and its motor proceeding is that of conscious volition. The clinical association of loss of memory and loss of volition is thus elucidated. It is significant that when hypnosis is induced it is also the memories of *conscious* experiences that are suppressed and those of *subconsciousness* that are thereby facilitated to their replacement, *i.e.* in substitution of the displaced memories. These instinctive and automatic activities are preserved intact, and *voluntary* performances are those contingent upon suggestion.

In hysteria the dominant proclivity is the enacting current thought as born of the senses and unmodified by the memory factor. The distractable mind of hysteria is one adrift in a sea of myriads of sense impressions, minus the rudder of memories of past experiences. Amnesia, in which the memory element is more or less effaced, is producable by hypnotic suggestion, artificially, as well as by pathogenic factors.

It is extremely significant that hysterical loss of memory, coincident with a hemianesthesia, is observed to be restored to normal with the restoration of the normal body sensibility, thus implying that the anesthetic regions of the body are the seats of the impaired memory. We, however, recognize that this would not be a legitimate deduction in the case of an *organic* hemiplegia due to a cerebral lesion. In the present class of cases their hysterical substratum, the amnesia, resulting from the anesthesia, and the incidental loss of memory concerning the related volition, and the fact of their coincident recovery, are at least significant.

We must rid ourselves of the old notion that *sensory impressions* so called, are in reality *impressions*, in the sense that impressions are made on a photographic plate. Every sense reception from the external world is a *reaction* phenomena, in which first the tissues of the sense organs, and reflexly, those *contractile* tissues which secondarily react to it, participate—as an associated ensemble. The typical features of specific subjective and objective perceptions are not *per se* typically *impressed* in the strict sense of the term, but are typical tissue reactions, and each is more or less currently modified by inter-reaction with past impression or reaction reproductions, which also in turn have been modified by their past, etc., *ad infinitum*.

The reproduction of individual experiences as memory, habit, automatism, etc., is a repetition, of the original reaction under the law of repetition, by virtue of which the definition, facility, and permanence of its reproductive possibilities are improved, in direct relation to its consecutive number of repetitions. We observe, however, that each individual instance is dependent upon the current state of the subject's sensibilities, and that participation in each embryo perception by anesthetic tissues is thus precluded. We have for our consideration numerous instances of narrowing of the fields of perception, of memory and of consciousness, by both direct and indirect localized anesthesias.

Loss or abeyance of the muscular sense involves only the *voluntary* muscles, since the *involuntary* are not dependent upon muscular sense and act when volition is thus inhibited. This fact alone would account for the action of *voluntary* muscles exclusively, when this muscular sense anesthesia is absent, and otherwise for the exclusiveness of action of the *involuntary* muscles. The involuntary muscles act exclusively of the conscious attention, so far as *feeling* is concerned.

The enfeeblement and abeyance of memory in hysteria and other neurotic states are such that outer sense perceptions fail to attract the languid consciousness, and they fail of elaboration into a *conscious* perception. The sequence is the occurrence of the so called hysterical or functional blindness, deafness and of anesthesia, which may range from absolute anesthesia of the sense organs, to impression—only in the subconsciousness, and find external expression only when the consciousness is in abeyance. Apparently the observed obliviousness of both attention and of memory are affections of diverse varieties of anesthesia.

There is exhibited a blunting of the sensibilities of the every day life vicissitudes of humanity outside of their own sphere of feeling and incidental volition. There is exhibited a limitation of feeling and action to a restricted field, from which they are loath to depart. The focus of the vital energy on the self constitutes self centering. This is common to cases wherein external sensation is diminished.

Selfishness, Egoism, and Egotism.—The perfectly balanced and vigorous mind can hardly be selfish, because it cannot be oblivious to any important social situation, either in transient intercourse or in more permanent relations. It must tend to be sympathetic, fair, and just, because it possesses that breadth and unity of view of which these qualities are the natural expression. To lack them is not altogether social or human, and may be regarded as the beginning or exhibition of degeneracy. Egotism is then not something additional to ordinary human nature, as the common manner of allusion suggests, but rather a lack, a void. The egotist is not more of a man, but lacks real manhood; and as regards personal power he is as a rule the weaker for his egotism.

The so called retraction of the field of consciousness of hysterical states is primarily characterized by a hyperesthesia, and, secondarily, by a spasmodic paralysis excluding the voluntary element of consciousness, and leaving the non-egotistic or involuntary ensemble as constituting the altered consciousness (the subconsciousness). Ethics which

is concerned in the attitude toward others is subordinated to selfishness. The inethical-unsocial feature is an incomplete consciousness, minus the fuller elaboration of those elements which go to make up that higher consciousness which combines other than the egoist features. The hysterical is thus exhibited as an unstable intermediate between the conscious and the subconscious phases, in which relatively slight causative factors bring about the subconscious by the suppression of the conscious. This so called retraction of the field of consciousness of hysterical states is characterized by an apparent hyperesthesia of the ego unit of volition which is productive of a corresponding anesthesia of the antithetical social and ethical elements. The physiological status of the stigmata are fractionally exhibited in their fullest waking state. They are thus much nearer the typical stigmata than the normal individual and are in a continuous state of predisposition to spasmodic completion of the stigmatic state.

We have pointed out the typical coincidence of *hyperesthesia* and a resulting *anesthesia* of stigmata. The world has ever taken account of the typical association of the hyperesthetic self centered egoist and egotist, on the one hand, with the unfeeling obliviousness of others, on the other. It is recognized by criminologists as the typical trait of the inherent criminal. We have observed it in the Bolsheviki, in the I. W. W., Anarchists, etc. We believe this hyperesthesia of the ego, accompanied by the usual anesthesia toward the outer world, finds adequate explanation in the above given hypothesis.

That trait of the typical German soldier, apart from his automatism and slavery to discipline, which makes him generally admitted the best soldier and the most tolerant of shell fire and explosion, is, we believe, his blunted sensibilities. The same may be said of the Turk and some of the Balkanians. The same is the explanation of their atrocious and barbaric cruelties and long list of unfeeling crimes. We have reason to believe them pathologic. We have seen their wonderful performances in exultant optimistic offensives, but we have yet to see them in pessimism and defeat. We should be slow to stigmatize the more sensitive natures among our own troops who are disqualified for the greater shocks of modern warfare as neurotics or degenerates, especially as partly based indeed upon an incapacity for alcoholic beverages. What diagnosis! Let us differentiate genuine neurotic stigmata from the features which go to make the best conscientious and public spirited citizenship in time of peace.

We learn from the observations of Freud and his school of psychoanalysts that the primal impulses are much more highly represented in the *subconscious* than in the *conscious* mind. Observers of the pathogeny of the war neuroses allude to the exhibition of subconscious expressions of the ascendency of the dominant primal impulse or instinct of self preservation which may override all other influences, as a sequence of the vicissitudes of war. We have observed that the exaggeration of the ego of the neurotic and sense of aversion to or abhorrence of anything like laborious work of the irritably weak, is characterized by an unconscious shrinking and evasion which dominates the disposition, overbalancing all other desire and ambition. This is typical of the malingerer.

Egoism Versus Volition; Willfulness and Deficient Control of Will.—Probably there is nothing within the realms of psychology which presents a greater paradox than the use of the terms ego—will—volition, etc. The subject of free will has formerly been such a bone of contention in theology that it has been unceremoniously dropped for the good of theology. Science cannot do such things. As a subject in psychology it must be faced squarely, its problems met and conquered.

We are still facing the dual theism of the pilgrim and the devil (the tempter). The individual self, the ego, is the pilgrim, the master of a free will, an eternal soul temporarily located in a mortal body which serves as its instrument and obeys its will, when not possessed by the devil, or after it has been cast out by a divine incantation. The soul is represented as a free discriminating agent steering an elective course for good or ill dependent upon one's luck in choosing between the competitive solicitations of good and evil spirits.

Let us start out in an adventure of psychological analysis from the above given standpoint and see where we land. Our first subject for analysis is one who is struggling to do right. He is religious in the extreme, he is doing everything in his power to conform to religious dogma and formula in order absolutely to insure the eternal safety of his soul on which he places the highest value. He is egoistic, willful, and self assertive to the last degree and without tolerance of those who reject his formula of salvation. He is truly anxious to conduct himself ethically, yet he lies, steals, indulges in sexual vices, etc. Psychiatric experts say he is weak-willed. He lacks control. He is weak in restraint of powerful impulsions and compulsions. He wills to crime and lacks in restraint of execution. If he encounters resistance he exhibits any degree of violence necessary to get through. In other words, he displays strong will and energetic execution in wrongdoing, but for a will to abstain from it he is said to be weak. Perhaps this is an exhibition of "malicious animal magnetism" on the part of the devil. Are the commissions of crime exhibitions of free will or lack of will? Are they sequences of volition or lack of restraints of *primary* by *secondary* elements of mind? We hold the latter view.

The will of the subconscious concert is unconsciously pitted against that of the conscious. The will of the subconscious impulses encounters the will of the full conscious, the *attentional*, which is a higher elaboration of the same sensorial preamble, the first being the subconscious non-voluntary, and the second the conscious, the voluntary or egoistic ensemble. The simplex (the subconscious impulses) encounter little or no retardation of an interrelation with past experience, and whether a spontaneous expression of primal impulses, a transient reverberation of a past reaction, a memory, or an impetus from a passing sensorial impression exciting a motor reaction, it finds expression unmodified. Conversely, the matured reaction, elaborated and modified by a past experience, expresses a volition which is thus normally egoistic, and the composite of the ensemble from which it emanates. The motor expression implies muscular sense on which it de-

pends. Here we apparently observe an hyperesthesia unmodified by anesthetic retardation.

The Sthenic Hyperesthetic.—As distinguished from the *asthenic* type of hyperesthetic manifestations such as is observed in neurasthenia, the *sthenic* type is perhaps best portrayed by the personal traits, character and mental characteristics of the German Kaiser as they are depicted to us in current literature. Prior to the consideration of these, however, we may take note of the undeveloped and deformed left arm as a possible *physical* sign of degeneracy, by disregarding the several conflicting stories that are current, which imply that it is simply a case of muscular atrophy from a late post-partum injury, but which appears to be contradicted by its deficient length and other developmental abnormalities. As descriptive of *hyperesthesia* in general, he is said to be irascible, tensional, high strung, petulant, restless, loquacious, impetuous, impatient, unenduring, intolerant, and unconstrained. *Instability* is implied in capriciousness, inconstance, disloyalty, unscrupulousness, hypocrisy, perfidy, treachery, and emotional instability of sthenic type. Recent reports imply unrestraint of the depressive emotions. *Sthenic* attributes are represented in his exaltation, imperiousness, ostentation, vanity, conceit, pomposity, arrogance, self-glorification, braggartism, presumptuousness, hypercriticism, dictatorialness, domineering proclivities, tyranny, high-handed despotism, and abuse of power.

The above are, however, counterbalanced by features which are usually classified as *asthenic*, indicating inherent weakness, deeper than nutritional sthenia, namely, the constitutional weakness or inferiority of heredity. These are evasiveness, sly cunning, deceptiveness, his intrigues, subterfuges, secret agent knavery, and insidious propaganda. Perhaps yet more indicative of *antisocial traits* are his self-centering, self-consciousness, selfishness, self-love, venality, avariciousness, his underhanded and cowardly tactics of warfare, his sentimentality, and pronounced religiosity. Typical criminal attributes. His *criminality*, by his royal and imperial prerogative, includes wholesale and wanton murder, rape, rapine, superatrocities, vandalism, arson, general devastation, and international brigandage. *Anesthetic* traits are observed in his exhibited callousness, moral hebetude, stolidity, ruthlessness, and unpitying barbaric cruelty and inhumanity as dictator and unfeeling spectator of wholesale human (and as personal perpetrator of animal) slaughter. Among *spasmodic* characters exhibited may be mentioned impulsiveness, rashness under excitement, obsessions, fixed ideas, opinionatedness, willfulness, and zealotry.

Probably few men in history could provide more signs of degeneracy, mental, moral, and physical, thus unified in a single individual, than William the Second of Germany. Many persons of unimpeachable veracity, who have been in position to know, affirm that the Kaiser *personally* is responsible for the unscrupulous and frightfully barbarous acts of the German State, army, and navy.

Within a very few years our newspapers have chronicled the visits of the Kaiser and his retinue to his hunting lodges on the Prussian crown lands, at which he gave vent to his mastering passion for cold-blooded butchery. The annual game roundup into the great drive pens converging to a narrow passage through which the panic stricken deer are driven, finds the Kaiser standing safe in his contiguous royal box, and together with his guests pouring torrents of lead into the bodies of the defenseless and flight precluded animals.

The unsportsmanlike character of the "pot hunter" has ever excited the contempt of all manly men, but the infinitely more cowardly and cruel massacre of these close grouped, helpless herds, of an inevitable death in which they were deprived of modern slaughterhouse humane butchery, is only equaled by that same Kaiser who journeyed to the North Cape to escape the responsibility of declaring war, by him who authorized the frightfulness campaign of murder, rape, and rapine of defenseless women, children, and the aged of Belgium, France, Italy, Servia, and Roumania; who seized upon the sneaking submarine to send to watery graves inoffensive passengers of noncombatant unarmed Atlantic liners with their precious cargoes of women and children, who lowered diplomacy to the level of confidence trickery and chicanery; and civilized warfare to the level of barbarism and most brutal savagery, in which soldiers are taught such tricks as malicious attacks after surrender, and upon their rescuers when wounded, and he who resorts to decoy, deceit, and humbuggery in peace treaties to subjugate the unwary; who seeks by bribery, misrepresentation, and fraud to seduce those he cannot defeat; he who is seeking a conquest of the world by debauching it, and destroying what he cannot steal or subjugate. Such a beast all the world is fighting and he must be punished notwithstanding our recognition of his degeneracy. He must be made an example of for the good of the world's future.

Diagnostic Hints.—The exhibition of astasia-abasia, in which the patient experiences inabilty to walk or stand, or to command coordnation and muscular control over the legs, when in the erect posture, should cause the physician to look for splanchic venous stasis with circulatory discompensation and for compensating tachycardia, with either a transient rise of blood pressure or circulatory failure. The abrupt and pronounced shock cases exhibit more marked circulatory disturbance and are correspondingly easier to diagnose than the fatigue exhaustion cases.

Cases exhibiting syncope, vertigo, anorexia, blanched and cold peripheries, cold extremities and labial and digital cyanosis should be regarded as exhibiting some degree of splanchic venous stasis even before pronounced circulatory failure is observed. In greatly prostrated victims of shock of the largest shells, it is well to percuss for dilations of the heart and stomach as soon as emergency factors permit. These should be outlined and retraced on architects' tracing cloth and preserved for record and comparison.

All fatigue cases exhibiting albuminaria should be recognized as vulnerable to shell shock, and shell shock cases, as probably already exhibiting an acidosis, which should be tested for. (See 37, I.)

Hyperglycemia being a common product of violent recoils, to chill and mental and moral shocks, should be carefully sought by a series of urinalyses for sugar in all hysterias, anxiety neuroses and shell

shock cases coming to the field as well as base hospitals. Our reports are negligent on the result of such tests.

Marked somnolence should suggest the presence of the diabetic syndrome, and be tested for accordingly (sugar, acetone, and acidosis).

Exophthalmus, and thyroid and other vascular swellings should be carefully observed and thoughtfully reported in case records. Even if at the time without diagnostic significance, they will always be valuable for statistical purposes and for the later interpretation. When hypo-thyroidism is observed, thyroid feeding may prevent the onset of subcatalysis with corresponding lowering of tissue density incident to impairment or arrest of the oxidation synthetic processes.

The development of anxiety symptoms should not to be too precipitately judged to be wholly neurotic in nature. Attention should be attracted at once to the circulation, and prompt measures provided against decompensation before the other and more alarming symptoms of circulatory failure supervene. The socalled *cardiac* anxiety symptoms, it should be remembered, are really *circulatory* indices, with cardiac failure as a single possible factor thereof.

Treatment of the Physical Disability.—The ideal prophylactic and therapeutic measure for fostering physical conditions which are incompatible with a spasmodic periphery, is the production and maintenance of the best possible conditions of *active,* as distinguished from *passive* hyperemia, thus promoting an *active* circulation, as distinguished from a stasis of the blood flow. The so-called passive hyperemia which merely constitutes a dilation of the superficial vascular system, such as is produced by heat, the Beer's treatment, and allied measures, are productive of stagnation of the superficial circulation, and as such are causative of low density and spasmodically predestined tissues.

The *immediate* effect of hot baths and passive hyperemia treatments in general is favorable, to be sure, but the *ultimate* effect is the very contrary of it, namely, one fostering stagnation of the peripheral circulation and low density spasmodicity of the superficial and extremity tissues. Unless repetition of emotional, hysterical and shock spasm events are interdicted, the remedial measure is defeated. The production of active hyperemia is dependent upon active peripheral stimulation, and the best ultimate effect results from the tissue condensing effect of cold, rather than heat, but chill *per se* is immediately productive of contractile exsanguination of the periphery and therefore the temperature must not be excessive or beyond the attainment of an immediate counter reaction attended with *active hyperemia.* Such a reaction is attained by a combination of active stimulation of the surfaces of the body by the rubifacient effect of ingredients added to the bath water, warm towel drying by enveloping the body in warm sheets, brisk frictional rubbings and spattings.

The more stimulant the carbonic dioxide, the alkaline earth, the saline, pine needle, or mustard ingredients of the bath water, the greater is the tolerance to cold with a safe hyperemic reaction assured. The personal equation of each case, however, must determine the temperature permissible and the reaction measures necessary. The application of this part of the treatment conforms to that adapted to cases of cardiac discompensation as we have heretofore more elaborately considered it." The technique of this treatment acquired by us at Bad Nauheim in 1900, together with the theory of the same since enunciated as above cited, have been endorsed as correct by Prof. Theodor Schott. We may also add here that the theories of the physical bases of the psychoneuroses herein set forth are founded upon clinical studies and observations made at the Salpêtrière under Charcot and his contemporaries in 1892.

Remedial relaxation of painful cramps, tetanically caused anesthesias, etc., may suffice for a cure, if the exciting cause is past and the predisposing hyperesthesia is also abolished; otherwise recurrence of symptoms, after artificial anesthesia, is prone to occur in aggravated form.

We must not disdain to cultivate cheerfulness and optimism in these patients because they have relatively recently been dubbed *New-thought;* it is as old a practice as medicine itself and has been almost universally practised and recognized by medical authors as a valuable agency in all indicated cases. The only thing to be shunned is that shift to the other extreme that counts all afflictions of mankind as imaginary ailments which may be dispelled by a sufficiently complacent denial of the malady, and thus neglects often much needed *physical* treatment.

Certain emotions and impulsive acts appear to be characteristic of a border line phase between the psychic and the motor, partaking of both, more or less, and .oscillating more or less from one to the other. They retrogress into the spasmodic events, or progress toward recovery according to the manner of handling the case, as we have outlined.

Oppenheim's[2] inhumanly painful treatment of shell shock cases is based upon the theory that the affliction is *psychic* in nature. The consequence is that the real physical status is neglected and the fundamental basis, the hyperesthesia, is increased and the ultimate effect is sacrificed for the current one by a process of applying a treatment worse than the disease. Such treatment is not desirable even from the economic standpoint. Its ultimate results are most unfortunate. German desperation to free the hospitals and get the men back in the ranks regardless of ultimate economic capacity of the victim would not be a wise course for our country to pursue.

Danger lies in taking the hysterical excitement and the confused states of the war neuroses, which may clear up in a few days, for indices of recovery, instead of the exhibited conditions of irritability, fearfulness and emotional instability which may last for weeks. *As long as hyperesthesia persists there is danger in returning men to the fighting line.* The next knockout, which they would be predisposed to, might prove their permanent undoing. Hyperesthesia is the safest index for prognosis.

Therapeutic measures of diverting the patient's attention for the relief of the tetanic stress inhibiting articulate speech, attain their ends, when

they succeed, by virtue of the release of the superstress of the spasmodic contractions which abort these efforts. The successful outcome is attained when the tongue and labial muscles become even momentarily tension free, and permanence is born of the experienced facilitation of function and the attending restoration of self confidence.

Recapitulation and Commentary.—1. Tissue density is an index of existent tissue integrity, and both are more vitally dependent upon incessant oxygenation and oxidation than upon food or water for their consecutive maintenance.

2. Corresponding *decrease* in exhibited physical strength, and *increase* in irritability and reaction velocity, attend falls in tissue density from all causes.

3. Hyperesthetic reaction is the direct sequence of excessive irritability of the tissues and is characterized by corresponding precosity and dynamic redundancy of reaction. Its physical expression is therefore contractile phenomena occurring as reaction to superacuity of sensation.

4. The exhibited contravention of physiological rest and recuperation by the continuous tetany and excessive reactions, tonic and clonic contractions, due to the superirritability, the premature discharge of potential and kinetic energy, and the production of fatigue products in excess of oxidative combustion (which is seriously diminished) and elimination, are responsible for precocious and excessive fatigue and of exhibited premature exhaustion.

5. The experienced sense of weakness, the physical incapacity, that fluttering, quivering, tremulous, shaking, jerky, shambling, writhing and convulsive phenomena are without exception contractile in nature and are examples of incomplete contractions, or of broken integrity contraction disorders. Stuttering, stammering and other disorders of oral expression come within this group. Spasmodic starts, fits, "jumpiness," etc., are examples of hyperesthetic recoils to factors insufficient in dynamic value to thus excite normal responsiveness, on the one hand, and to excessive causative factors, on the other.

Tetanic constrictive contractions of tissue areas, peripheral or extremity, which may be transient and fleeting or stationary, are responsible for exsanguination asphyxia and consequently of anesthesia of the affected areas of tissue. Thus is hyperesthesia a predisposing cause of anesthesia.

7. The great typical feature of hysterical paralysis and amnesia, and of paralyzed arms and legs, is anesthesia, which involves loss of tactile and muscular sense. The sense of weight and deadness of paralyzed limb is due to the loss of muscular sense, which is a sufficient factor to defeat the exercise of volition, unless the sensorial break is compensated for by another sense such as vision. Constructive motor images of new volition syntheses, exhibited as repetition phenomena of past performances, are made impossible by the abolition or the abeyance of the muscular sense impulses from the involved tissues.

8. All known examples of extremity asphyxic gangrene, both wet and dry, are attended with anesthesia corresponding in time relation with the asphyxia; some of these anesthesias are preceded by hyperesthesia and painful contractile phenomena, which here obtains above the margin of anesthesia.

9. All such instances of anesthesia are *immediately* relieved or benefited by relaxing, by sedative, narcotic or anesthetic measures, and not by their antitheses, showing an underlying hyperesthesia which would be increased by exciting and painful measures.

10. Relaxation, however attained, is transient in time duration, unless the underlying hyperesthesia is primarily abolished, and in the presence of the hyperesthesia, continuous warm baths and drug narcoses cause yet lower tissue density, predisposing to recurrence, and in the case of the latter to drug addiction. The reaction is typically hyperesthetic, following all narcotic and other artificial anesthetic actions.

11. The provisional recondensation of tissue produced by the hypodermic administration of asepticised ergotin, the rectification of the disequilibrium of the blood by adaptation of cold or cool baths, with the cold provided against by stimulating and rubescent ingredients as carbonic dioxide, pine needles or mustard, etc., and by warm towel sheet envelopment of the body and brisk frictional rubbing until a distinct surface glow is attained, followed by an hour's rest, and after a few hours' interval by massage, and first resistant and later graduated active exercises, constitutes the general treatment which we commend.

12. The anorexia of the hysterical condition, which we now believe to be caused by splanchnic venus states,[2] even Sollier at one time believed to be entirely mental. He then wrote: "To my mind there is but one kind of nervous anorexia, namely, mental anorexia." Charcot[7, 111] showed that the psychical factor plays a prominent part in its causation, to which we agree. It is, however, indirect. The occurrence of splanchic venous stasis, from all causes, is prone to cause correspondingly severe cases of nausea and vomiting. As biliary and other associated organs are similarly affected the anorexia becomes correspondingly greater. The same cause produces psychic symptoms.

13. Throughout hysterical manifestations there is exhibited a consistent series of motor disturbances which are, significantly, difficulties of various degrees of coordination, of systematization and unification of motor responses. The motor portion of reactions, starting with the sensatory preamble, are broken or disqualified in the intermediate phase preceding elaboration (1), whereas the memory factor intercedes, or (2) in tetanic defeat of an oriented finished product.

14. Catalepsy and contractures disappear with return of muscular sensibility, and momentarily when the attention is aroused. As a sequence of hyperesthesia, the hysteric is in a continual state of predisposition, to a readiness for contractile tetanices such as contractures and catalepsies.

15. The special senses of sight and hearing, in particular, are in some cases or stages rendered hyperesthetic and give vent to hallucinations and wild deliriums. In others they are rendered anesthetic and are attended by the so-called hysterical blindness and deafness. The fact that the greater number of causes of paralysis and hysterical con-

tractures were accidents other than caused by great physical traumatisms, only emphasizes the fact that a greater hyperesthesia, a no less physical manifestation, compensated for the lesser traumatic injury or recoil. Our evidence that the reaction violence is an excessive *tissue* reaction is not controverted by any evidence that it is due to an electrical discharge from the brain or nervous ganglion, as per the torpedo fish. One might go farther than the statement that *there is no mental apart from physical functions*, and we add that *all psychological images have a motor side.* Even visual hallucinations are commonly attended by movements of the limbs in accord with the subject on the mind. Dreams cause motor exhaustion occasionally.

16. All intellectual workers appreciate the importance of a circulatory equilibrium in sustaining mental capacity. Not only by recumbent or a semi-recumbent position, but by warm lower extremities and a cool head. Circulatory compensation is second to no other factor as a determinant of consciousness and of mental capacity. It is a much neglected factor in cases of mental and emotional disability in general.

17. Janet[15] admits that disorders of sensibility and particularly anesthesias follow spasm. He also recognizes that hyperesthesias engender spasm. Thus both phases of the process are separately admitted by an official exponent of the Charcot school, the stronghold of the psychicalists.

18. Janet is obviously wrong in referring to the related incomplete anesthesias as due to fixed ideas and to *false* anesthesias, because not complete. It seems obvious that the anesthesias here proceed as the predisposing causes, and the fixed ideas represent the tetany resultant. Some cases, however, may exhibit a vicious cycle of mutual interrelation.

19. The status of a case wherein *anesthesia* is exhibited, other than when conscious attention is attracted, and then the exhibition of *hyperesthesia* follows, suggests the relationship of the *subconscious* with the *involuntary*, and the *conscious* with the *voluntary* muscular systems, the subconscious ensemble carrying the fixed ideas. This is vital and worthy of further investigation.

20. The emotional stage of hysteria is not that of developed stigmata but of the preceding stage of predisposition to the stigmata. The hyperesthetic stage is the emotional one of spasmodic proclivity, but not that of anesthesia, of catalepsy, of contracture or rigid or flaccid paralysis. The fixed ideas which an original hyperesthetic stage formulated, the outgrowth of its timorous sensibilities, its fears, anxieties, worries, distressing solicitude and apprehensions as selfish interests, self love and pity, and in general self absorption, with the balance of humanity excluded, become fixed with spasmodic events, and tide over as fixed ideas to succeeding hyperesthesias and tetanies where they find favorable soil and vegetate—influencing the thought and life of the victims. The fixed idea becomes a *menace* to the patient when it is expressed as an anxiety, a morbid solicitude, anxious apprehension, an irritation, a source of discomfiture, of discomposure, of fearfulness, of disconcertedness or as a source of fret or worry, vexation, of dismay, dread, alarm, of surprise or distressing anguish. A subconscious anxiety, a fixed idea, as a tetany and a resultant anesthesia of the muscular sense (amnesia), acts as in hypnosis as a suppressor of memory of the conscious state and a segregated dominator of the voluntary muscular system, acting as a stress factor.

21. The depressive and pathetic emotions are most emissive in type; and those of fright, anger and rage, in the strong, and the conversion or motor type, are least so. *Motor* expression involves *hysterical characters.*

22. The disappearance of emotionalism, hysteria, automatic writing, suggestability and other characteristic phenomena in old age, evidences the fact that loss of water content in the tissues of the aged ends the low density reaction manifestations of earlier life.

23. General artificial anesthesia releases the events of shock, the affected parts or areas of which are probably already anesthetic, demonstrating that the cause is contracting rather than relaxing.

24. In general, violence and time duration of motor reactions occur in inverse ratio, one to another. The greater the violence exhibited, the less sustained it is. In other words, the accrued energy is expended correspondingly earlier—relative to its intensiveness and velocity. The converse is equally true within normal limits, whereas beyond the normal boundary line torpor, motor slackness and asthenia more commonly coexist.

25. In general, whatever motor act finds expression with a minimum of resistance, we term a voluntary act, whether it proves to be well advised or not. One may commit a crime, at the moment voluntarily, yet regret it almost immediately afterward. Impulsive and intuitional acts, however freely committed at the time, are not infrequently later characterized by the commissioner as involuntary. We are thus brought face to face with the problem of determining a line of demarcation in individual cases where the *involuntary* ends and the *voluntary* begins.

26. The question often arises in cases of mental conflicts, which is the will of the ego; the spontaneous impulse, or the restraining or repressive element. One may be dominant on one occasion and the other on another occasion. Either may happen to prove the pragmatic one. Restraint may be in error. The exclusion of the memory factor of the subconscious state involves the loss of the I, the individual character which in turn involves the corresponding diminution of the will or volition which is dependent upon the ego for its very *voluntary* attribute.

27. To the scientific physician, the mind is the function of the body, and there is no physical which is devoid of its mental aspects, and no mental apart from the physical. Both are expressions of the collective physical body. Sir Charles Bell, in man, and later Charles Darwin, the latter with greater completeness, elucidated the anatomical expression of the emotions in man and animals, all emotions, painful and pleasurable coming within the physical range of contraction and relaxation.

28. The mental relations of the emotions have to do with the time, place and interrelations, and of the sense perceptions of the emotions expe-

rienced, as well as the modifying influences of the individual's past experience. One may view the emotions from the anatomical viewpoint, or from the physiological point of view, as related to hyperesthesia, deflections of great volumes of blood, peripheral anemias, and asphyxias, anesthesias, contractions and relaxations. One may view them exclusively from the standpoint of the mental relationships, but both are equally unscientific. True science knows no fear or favor. The truth and nothing but the truth, the dictum of the judiciary, must prevail in scientific medicine and not less so in any psychology that is to endure. We may recognize all *mental* aspects but still remember when abnormality occurs the *physical* substratum is at fault and must be properly reckoned with and corrected.

29. Charles Féré[2] has observed that a violent emotion is as capable of provoking a drunken delirium in a chronic alcoholic as is a traumatic shock or an acute illness. Conversely, alcoholism predisposes to emotionalism. National prohibition during the war will not only save thousands of our soldiers from war neuroses, from both hysteria and shell shock, but it will otherwise save millions after the war, if it continues as a permanent institution, with the people free from vulnerability to other emotionalizing influences, and we will become a more stable people—socially and morally. Whatever causes or augments emotionalism is a menace to any people, but particularly those with republican forms of government. Emotional instability is a vice that threatens the state which depends upon the mental poise of its enfranchised citizens. Russia's revolution is an ever living exemplification of that. With the accession to power of the Bolsheviki, vodka and social license were simultaneously given a free hand. The reign of terror followed. The Russians, naturally a phlegmatic people, became, thanks to vodka, the most unstable.

30. The terms phobias and fears symbolize symptoms arising as pathologic states in the absence of actualities warranting fear as a normal apprehension or cause for solicitude. Morbid fears and phobias represent more definition and fixation of ideas than mere anxieties, which may be diffuse (cardiac anxieties for example). Both are fundamentally expressive of irritable weakness, the sense of weakness characterizing the absence of confidence and defensive stamina. The return of strength, sense of capacity and therefore of self-confidence, marks the disappearance of morbid fears and anxieties. The initial appearance of anxieties marks the onset of irritable weakness, *asthenic*, as distinguished from *sthenic hyperesthesia*. When they become identified with fixed ideas developing into definite subjective or objective fears they indicate the transition from a tetany to a spasmodic character of reaction, and exaggeration of acuity and intensity of recoil; and emotionalism and other spasmodic events are exhibited.

31. Physically, anxiety is a tetany, fear is a rigor or tremble (relative to contractile integrity), fright is a spasm, and terror is a paroxysm. Except for the physical character of these contractile phenomena they would not prove so exhausting.

32. Whatever be one's estimate of the functional advantage of the undulatory phenomena produced by chill and termed shivering, we cannot ignore its close analogy to the tremors which obtain as sequences of traumatic factors that drive the blood from the superficial circulation, of cardiac incompetence and the resulting circulatory discompensations, and of hemetic anemia, all of which in the last analysis produce peripheral and extremity anemia and are productive of those vibratory flutterings and shaking and quaking types of broken integrity of contractile phenomena which is exhibited in movements and sustained efforts. The tremble of weakness and fatigue exhibits the same type of disturbance, and the quivers of the lips, which organs so early exhibit cyanosis in circulatory failures, are concerned in oral disturbances in the less debilitated cases.

33. The Shakers and Quakers, in their religious emotions and ecstasies, exhibited tremors and coarser shakings as stages in progressive syndromes which often extended to tonic and clonic contractions, and even to trances, hallucinations, etc. The economic value of all tremors and shivers as reactional manifestations depends upon the degree of *active hyperemia* they may be able to activate in compensation for, or in overcoming the peripheral *anemias* that produced them. The Shakers attained a pleasant glow from their shakings which constituted a sort of spree. In the case of chill, moderately low temperatures produce perceptibly warm reactions as shown by thermometers, but not by feeling. The sense of chill that activates it predominates. Shivering reactions are not developed by very low temperatures or tremors in the most extreme prostrations. Tremor requires a certain degree of vitality which is yet insufficient to sustain contractability of unbroken integrity. It is an intermediate (immaturely developed) contractile phenomena. It has its analogy in the vibrating flame of the lamp as the oil burns low and the supply falls below the demand of the burner.

34. After pointing out the dependence of the hypsterical and other neurotic manifestations upon a low tissue density, and that such degraded tissue integrities are in turn resultant from imperfect synthesis; we have been able to produce evidence of the exhibition of war shock conditions producing such effects. We have chronicled observations of deoxygenation of the air with explosive disengagement of a great excess of nitrogen, of asphyxiation by burial, of deoxidation of the blood with a surcharge of nitrogen destroying the ON equilibrium, CO poisoning, of a lowered alkaline reserve (acidosis), of peripheral and extremity volumetric anemia, and of splanchnic venous stasis; and of symptoms characteristic of low tissue density; both independently and as due to suboxygenation, suboxidation and subalkalinity factors.

Since the gross organic lesions are inconstant, the symptoms in their absence are of necessity incident to other causes, but since we now have proof that even hysteria fundamentally arises from physical causes, we must arrive at the conclusion that the universal factor is neither a gross lesion, nor is it psychic, but some other which is present, at bottom, in all cases. This factor must be due to the collective causes which are shown to be op-

erative in all cases exhibiting these manifestations and be shown to produce the final symptoms which are exhibited in these cases. What other than the tissue density factor meets all those requirements?

TONIC SPASM AS A CAUSE OF DISABILITY, AND THE REMEDY.

BY J. MADISON TAYLOR, A.B., M.D.,

PHILADELPHIA, PA.,

PROFESSOR OF APPLIED THERAPEUTICS, TEMPLE UNIVERSITY, MEDICAL DEPARTMENT,
AND

EDWIN CORDERY LEE,

PHILADELPHIA, PA.

So dominant and obdurate is the factor of tonic muscle spasm, acting as it does as the chief cause of disability in a variety of abnormal states, that we offer this brief preliminary note in the hope of directing attention to the possibilities of relief which a mastery of the condition opens up. We have cooperated in a number of cases where spasm proved to be the crux of the trouble, which had in most instances resisted all previous forms of treatment, constitutional or local.

The main or outstanding cause of tonic spasm may be ascribed to any agency capable of compelling a muscle, or muscle group, to assume compensatory function whereby relief is afforded to pain arising in another part. This familiar phenomenon may take the form of a local strain; most often a pain is produced which later sinks below the threshold of consciousness, no longer being interpreted as recognizable suffering, but which none the less dominates or impedes action, hence causes an involuntary overtension and shifting or alteration of attitude, also often causes a deformation, or an apparent displacement. Its economic purpose

is to protect instinctively an oversensitive or overstimulated structure.

The primary cause may be a focal sepsis, an inflammation, an injury or some traumatic disturbance of the bony relationships, especially of the delicate and sensitive structures about a joint; *e. g.* the sacroiliac, the shoulder, the wrist, the hip, the knee, or the neck. It may remain and disable for weeks, months, or even years.

Tonic muscle spasm is nearly always designed to furnish a protection. This it does more or less well for the time. The chronic pains and limitations of movements in joints are often the conditions which bone setters so brilliantly cure by "replacing" them. They do this by a forcible overstretching of the part, throwing the hypertense muscle out of commission, and also by stretching the tendon or ligaments affected. The sufferings caused by tonic spasm are of the nature of, or parts of, transferred pains.

In order to relax a state of tonic spasm the muscle affected should be induced to make a normal movement and against resistance; in short, to carry a load to the limit of its ability to contract, which may it be little or much, all the resistance it is capable of opposing may be exerted. The object is to persuade the muscle to make a movement which is normal and to divert it from a movement which is abnormal; also to place the impaired muscle or muscle groups in a position to functionate advantageously.

Next employ the antagonistic muscle against full resistance (contrary to the load), inducing it to act as far as it will go *without pain.* Should pain be caused in any instance it is by reason of having exerted too much or too long sustained effort, which causes groups of new muscles to come to the rescue, to grow overtense, to become fatigued in turn, hence to get into tonic spasm. These, then, try to take on function, to protect the impaired parts, in short, to compensate or adapt. Hence the "load" applied, or effort made, should not be too great to permit moderately free movements. Repeat these movements and the excursus will be found to increase. For example, in directing the action of a partly paralyzed arm in flexion, when it can pull no further and compensatory muscles begin to act, then suddenly cause them to reverse the motion, to extend. Then throw the muscles which attempt compensation out of action; through this device it is possible to make a new attempt to flex and thus secure fresh gains. Several repetitions will achieve the desired motor equipoise.

A muscle when in static contraction and employed in one direction will, when employed in a reversed direction, induce a "jerk" as the muscle in spasm lets go and its antagonist acts. Sharp contrasts in movement seem to induce overaction, *i. e.* to cause jerks, rapid alternations composed of sudden pushes or pulls; hence follows a motor bewilderment. This is probably due to muscles which attempt to compensate and aid in a movement, and which are thus thrown out of action when the movement is reversed.

For example: a man who can move his neck to the right but cannot move it to the left, except a short distance, is told suddenly to shift to the right against resistance, then suddenly to the left and he can thereupon go a half inch further. If he is urged to go further to the left, he fails to do so, but he makes other "false movements," *e. g.* he lifts his shoulders or throws his head back in an attempt to execute an equivalent, but not the desired, movement.

It is possible to go further to the left at that stage, in opposing resistance to the action toward the right. He thereby loses his head and shoulder movements to the left, which are false efforts. When next commanded to move to the left he will then be able to do so; to make an increased left normal excursion.

This alternating action is better than to urge him to move yet further to the left, which causes false head and shoulder movements. Also, a man paralyzed (partly) in his legs when attempting to walk forward tends to throw his body forward, hence to use the weight of his body to get him forward (to advance as he hopes to). Then command him to suddenly step backward. This calls attention to the fact that he is merely using his weight and not his leg muscles in the forward movement. This naturally leads to a better, more consciously controlled, attempt to co-ordinate his legs and thus increases his confidence in his powers to exert control, poise.

The desirable effect is to achieve conscious control, an intelligent direction of voluntary acts. In doing so the attention must be guided in a manner capable of producing understanding, obedience, and hence co-operation. The cases here referred to gained great confidence and co-ordinative power by holding a long stick directly over the head and pressed against the ceiling.

Movements can be made against resistance to a degree and power impossible without the stimulus of explicit guidance in direction and force. This dictum applies to free movements and not to those in opposition to a "load resistance." To push a mass (to raise a load) use flexion 50 per cent. and extension 10 per cent. Afterward add a full load and this acts as a guide and releases the 10 per cent. used to balance the muscle.

What we wish to achieve for the ataxic is biokinetic poise. Ataxia is of varied parentage; not always the clinical entity, tabes.

Under a full or heavy load, as Bucholz says, there is no undue intra-articular pressure.

In many instances where spasmodic conditions exist they are made much worse by manipulation, also by passive movements (done upon the patient), because the muscle spasm gets into yet greater spasm by the stimulus of effort or by submission to handling. Movements can be made against resistance to a degree and power impossible without this stimulus.

The way to relax the spasm is to give proper employment to the spasmodic muscle in its normal or functional directions and in holding or fixing the directly correlated groups.

ILLUSTRATION.—Dr. A. B.: Right sacroiliac and sacrolumbar disease. Subjected for nearly a year to many and diverse forms of scientific treatment, but as yet unrelieved. Confirmed by *x*-ray; joint wide open, admitting large finger.

Diagnosis: Spasm of muscles anterior to spinal column, *e.g.*, psoas, iliaci, quadratus lumborum, also spasm of other muscles. Lower dorsal and upper

lumbar vertebræ project prominently and posteriorly. His first protective action was to induce spasm in the left lumbar muscles; when these reached the limit of their endurance, the present spasms arose. The protective spasms become so intense they caused an aching in the protective group of muscles, and later in others; hence transferred pains occurred in various localities and groups of muscle fibers. Result, deformity and lameness of a different kind or quality. Our object was to relax these overtense muscles, especially at their insertion, where one over-fatigued muscle protected painful areas.

Procedures: The patient was placed in a comfortable posture; the overtense muscles were made to increase action in the direction of their attachments against resistance; they were guided by resistance to efforts to carry the load; to maintain compensatory poise. When no further action on his part was possible, the direction of the load was reversed. Thereupon a relaxation occurred at the time of change. The tonic spasm was unlocked, relieved, emptied.

While lying on his back (in dorsal decubitus) the leg was by the operator (passively) raised, flexed on body. Pain was not then caused in the overtense muscles, *e.g.*, iliaci and quadratus lumborum, but when he directed and impelled his leg in extension (in order to lay it down on a level with his body) it caused sharp pain in the sacroiliac region till down and fully relaxed. When resistance was offered to the downward movement, the leg being in the air, *e.g.*, the force of gravity checked, then the opposite group was employed and pain was relieved. The group affected was employed in extreme extension against a load permitting the flexor group to remain passive, otherwise both groups were employed to make a steady co-ordinated movement. Thus intra-articular pressure was increased making painful the diseased joint.

The sacroiliac synchondrosis could not be accounted for upon any other basis than septic focus from tonsils. These were removed long ago, but the sacroiliac condition and pain and deformity grew no less. The sensory and deforming states were rather increasing. So soon as the treatment was begun by us he began to improve and in about 6 or 8 weeks he not only recovered from the disabilities described, but in accord with his personal statement he had never been so erect in his life. He did appear distinctly taller. Also he became much more mobile, elastic, nimble.

Now it is our opinion, in which he agrees, that if he had recovered from his pain, deformity, and opening of his joint without other treatment than removal of tonsils and whatever medication had been employed, the recovery would have been by no means so early, so rapid, or so complete. We believe, and our experience justifies this view, that there would have remained some form or degree or measure of disability capable of serving as a limitation to his motor efficiency or normality and may have acted as the starting point of yet further disabilities. Certainly the recovery would not have been to the extent of his becoming straighter, more alert, of greater motor capabilities than before.

Systematic mobilization was employed throughout; also making more elastic his paravertebral and waist line structures; systematic education in points of view of his own state, of his interrelationships mechanical and psychic, by psychomotor and muscular education, passive, active, and aggressive, also by confident encouragements, suggestions, explanations, all of which were calculated to appeal to his good sense, his observation and training as a physician. The totality constitutes a pretty complete restitution.

The residue of the treatment consisted of judicious training of the muscles, mainly while lying down and by simple, carefully directed movements and resistances. Also the flexibility of the backbone, which was much impaired, was released and made pliant by "thrusts" (a la chiropractor), also by lateral movements after the muscles were relaxed, inducing a mobility most necessary in order to attain and also to maintain normal conservative, economic postures. We find this forceful (passive) mobilization of the vertebral column of constant value.

The muscular mechanism is for fixation and the nerves for control. A spasmodic area must necessarily have developed a special nervous and muscular mechanism which has also produced a group of structural peculiarities all its own. The reactions have changed in their degrees and also directions. From center to periphery there have come about inequalities of energizing and response.

If a part or a group of structures has been long under the influence of these irregularities, including strange, bizarre impulses and responses, when, after complete recovery, any unusual movement is attempted or some special and unfamiliar strain occurs, the result is an apparent return of the old disorder. The disturbed part has been for so long protected from strain or from natural movements by the spasm that a degree of hypersensitiveness follows effort. Hence any new movement elicits the protective reaction, a spasm or hypertension. Function is still bewildered.

This condition can be remedied by functional education only, by particularized movements under graduated strains, especially those less than customary and these should be gradually increased.

For example, if the part affected is one commonly employed in weight bearing, then give it functional treatment, *i. e.*, direct its use without weight bearing. Thus the load is steadily increased, the power is put on as the part can sustain it, till a new degree and kind of development or power transmission is attained and this reacquired or retrained power maintains the protection.

For example, in a chronic lumbago treatment or training should be graduated till the muscles fully relax, the overtense fibers cease to strain, and then they can be taught to do their normal work in the normal way. The final cure is by muscle training (bio-kineseatrics).

GINGIVAL SEPTICOPYEMIA.

By W. FOREST DUTTON, M.D.,
TULSA, OKLAHOMA.
MAJOR, MEDICAL CORPS, OKLA. N. G.

Diseases of the gums are an ougtrowth of civilization. Animals and members of the human family who lived in remote antiquity were free from diseases of the gums and suffered little from diseases of the teeth. The exhumed skeletons of mastodons, dinosaurs, and other animals which inhabited the earth in prehistoric ages show on examination perfect teeth imbedded in healthy alveoli. From these findings it is to be inferred that the animals' gums were healthy. Many tribes of people of the present, undefiled by the conventions of civilization, are free from diseases of the gingivæ. It can be said with a certain degree of accuracy that diseases of the gingivæ are a concommitant sign of civilization. Boasting of a progressive civilization, the physician and dentist are obligated to study, treat, and cure these diseases.

At this point I shall call attention to a disease that has been under my observation for some years. The condition is one I shall, for the want of a better name, call gingival septicopyemia.

Gingival septicopyemia is a local condition of the gums which rapidly becomes constitutional and is characterized by chills, fever, great prostration, hypertrophic spongy, suppurating, and

hemorrhagic gums, rapid hemolysis, acute nephritis, hemophilia, coma, and death.

The predominant etiological factors are pyorrhea alveolaris, traumatism, gingivitis, and alveolar abscess. The disease may occur following infection from a pick, brush, or other foreign body causing an abrasion, laceration, or permeable lesion. It is an infectious disease in which staphylococci, pneumococci, Klebs-Loeffler bacilli, Vincent's organisms, strèptococci (hemolysans, pyogenes, or viridans) actinomycoses, and other bacteria may be present.

There is a rapid hemolysis due to the virulency of the infection. There may be a leucocytosis at first, but it rapidly subsides. There may be extravasation of the blood in various parts of the body. If there has been pyorrhea alveolaris, or apical abscesses of long standing, degeneration of the liver and kidneys will be found.

Attending the etiological factors the following symptoms will be found: painful, tender, foul-smelling gums which rapidly become greatly swollen and spongy; chills, fever, and great prostration; oozing of pus and blood from the gums; ofttimes hemorrhage from the stomach, bowels, and kidneys. Cerebral hemorrhage followed by paralysis is not uncommon. The skin is pale, pasty, and frequently of a cadaverous character. The patient may become delirious and carphologia is noted. Pain varying from mild to excruciating in various parts of the body, is a common symptom. The urine is usually highly colored, albuminous, showing hyalin and waxy casts, and often much blood. Coma, as a rule, intervenes some time before death.

The prognosis is grave. Acute cases end fatally in three to five days. The subacute cases succumb within two to eight weeks. The diagnosis of this condition is not difficult as the source of the infection can easily be recognized. The only condition that may be confused with this disease is scorbutus. Scorbutus has many parallel symptoms, but is insidious and due to dietetic factors. At an early stage gingival septicopyemia is plainly in evidence. The occurrence of rigors, fever, sweating, and a foul, sweetish breath is very significant. The multiple, superficial abscesses will be observed in some cases. In others the signs and symptoms of metastatic abscesses will be present and evident by the cough, dyspnea, and localized condition of the lungs. There may be effusions in the pleurae and pericardium, peritonitis, splenitis, albuminuria, hepatitis with jaundice, suppuration of the joints, and various other conditions may develop.

In order to illustrate this condition I shall give the case records of one acute and one subacute case. These are selected as the most typical of twenty-eight cases that have come under my service.

C. F. N., an American master-printer of fifty-three, referred to me by Dr. Ira E. McCarty, came under my service in February, 1918. The family history is exceptionally good. The past history negative. The habits good except that he smokes a great deal.

The present illness began some time ago with pyorrhea. One week ago he was out automobile riding and "caught cold in his face." Two days ago his gums began to feel sore. He consulted a dentist who removed one of his teeth, believing that it would relieve the condition. There was profuse hemorrhage after the extraction, which was controlled with much difficulty. He has felt weak and feverish the last twelve hours and is very much exhausted. Physical examination shows a well nourished man, 5 feet 10 inches high, weighing 200 pounds. The scleræ are congested. The gums are greatly swollen, spongy, and oozing with puss and blood. The soft palate shows large spots of extravasated blood. The throat is pale. The apex impulse of the heart is normal. The sounds are distinct and of good quality. The pulses are normal. The lungs are negative. The abdomen is protuberant but its examination gives negative results. The skin has taken on a pale, pasty appearance. The genitals and pupils are normal. The reflexes are normal. Temperature 102° F., pulse 90, systolic blood pressure 120, urine: sp. gr. 1020; albumin in considerable amount, hyaline casts and blood. Blood: Hb., 85 per cent, leucocytes 21,080, polynuclears 68 per cent, coagulation time, 12 minutes.

The patient was treated symptomatically and all supportive measures were used, but he began to have profuse hemorrhages from the stomach, bowels, kidneys, and gums, and failed gradually. February 23 he died.

G. W. R., an American contractor of fifty-eight, referred to me by Dr. Ira E. McCarty, came under my service December 15, 1917. The family history was unimportant. The previous history was negative. He is an inveterate smoker; denies venereal diseases.

For three months he has had neuritis and able to walk only with the assistance of a cane. He has been treated for Bright's disease, rheumatism, and stomach trouble, with no improvement. One week ago he consulted a dentist, who advised him that his gums were not in a condition to be treated, and he was referred to an internist.

Examination shows a well nourished men, 5 feet 8 inches high. The scleræ have a bluish blanched appearance. The tongue is heavily coated, pale and flabby. The gums are painful, tender, and foul smelling, are swollen and spongy, and blood and pus ooze from them. Heart and lungs negative. Liver is somewhat enlarged and has a smooth insensitive edge. There is moderate edema of legs and ankles. Genitals and pupils normal. Reflexes negative. Temperature 100° F., pulse 80, systolic blood pressure 160. Urine: sp. gr. 1015, slight albuminuria; hyaline and waxy casts. Blood: Hb. 80; leucocytes 15,000; coagulation time 10 minutes.

In consultation it was decided to remove the patient's teeth as a measure to relieve the neuritic condition. December 16, Dr. Furrow removed under ether anesthesia 14 teeth, nine of which were abscessed. There was profuse hemorrhage immediately after the operation and for some days there was a great deal of oozing. The patient showed good improvement after this, was free from the neuritis and reacted well with supportive treatment and diuresis. The patient fared well for two weeks, then a uremic condition developed. Paraplegia, coma, and death ensued.

The treatment, whenever practical, includes the removal or thorough drainage from the focus of infection. The general strength should be maintained by fresh air, nourishing food, and strong stimulating tonics. In streptococcal infection an appropriate serum should be used. An autovaccine made from the focus of infection should be used. All sera in this condition should be used intravenously.

The prophylactic treatment of oral conditions cannot be too forcibly emphasized. An hour of prophylactic treatment is worth more than a month of curative measures. Prophylaxis should begin in early childhood if the more important diseases of the mouth would be prevented. The parent should be educated to recognize the fact that a great many diseases of childhood are due to oral conditions. The simple methods of cleaning may prevent the various diseases of child

and adult life. The great educational problem devolves upon the physician, dentist, and nurse. They are the teachers whose instructions should be made a matter of obligation and duty.

It is not the purpose of the writer to discuss at length the important subject of prophylaxis, but to touch only upon the salient points relative to the prevention of such a virulent condition as gingival septicopyemia.

Diet influences the growth and development of the teeth. In childhood the diet should be such that contains calcium salts sufficient for the healthy growth of teeth. The diet in the adult must not be poor in the elements conductive to proper nutrition.

Faulty nutrition in the child as well as in the adult, predisposes to early decay of the teeth and to a diseased condition of the peridental membranes.

Scrupulous cleanliness of the mouth is imperative. This is best observed by the proper use of plenty of water and a suitable tooth brush, rubber bands, floss silk, or a rubber bulb syringe.

A competent dentist is as indispensable as a competent physician and should be consulted at regular intervals (two months) relative to the condition of the mouth.

If there are deposits of either salival or serumal calculus, they should be removed. Decayed teeth, open contacts, imperfect previous operations (badly filled crowns, poor fillings) should be corrected. All pus conditions should be treated to remove the etiological factor. Teeth not amenable to treatment should be extracted. Diseased apices should be resected. All gingival inflammation should receive attention.

The teeth are, in a measure, the barometers of the health of the human organism. They are the crucibles which prepare the food for the laboratories of the intestinal tract. Any faults in the crucibles result in bad chemical mixtures in the system. The teeth may mean good or bad health according to their condition. They are to the esthetic aspect of the face what the mosaics are to the architectural structure of a building.

The physician, the dentist, and the nurse are the keepers of their patients, and it is a paramount duty that they at all times exercise their prerogatives relative to the care and treatment of the teeth.

603 New Wright Building.

SOME OBSERVATIONS ON THE NATURE OF CANCER, WITH SPECIAL REFERENCE TO UTERINE DISEASE.

By HOWARD CRUTCHER, M.D.,
TULAROSA, NEW MEXICO.

All known forms of life are distinguished by two great periods, the period of development and the period of decay. While organic life is less durable than inorganic, change or motion is characteristic of both. Man, in spite of his absurd egotism and his incessant labors in the field of self-laudation, is of no more importance in the general plan of Nature than a blade of grass or a fallen leaf. Moses, the most eminent man of letters who ever lived, painted such flattering pictures of man's supreme importance that all writers of inferior note have fallen quite unconsciously into the style of that unrivaled leader. This philosophy will explain why man has been so tardy in making a devoted and determined effort to study the real facts of Nature as revealed by her own works.

Cancer is a disease of the period of human decline, of decay, of atrophy. That some lover of controversy may not bring forth exceptions, I admit them in advance, without reserve, but the cancer patient is on the down grade of life. Cancer originates in glandular tissue, and during the period of its limitation to such tissue its progress is usually slow. The more compact its structure, the slower the growth of the tumor. It is undoubted that a small number of cancers remain inactive for years.

The child-bearing period of woman is between the years of twenty and forty, during which time the uterus and the breasts, these being the most frequent seats of cancer, are notable for extreme functional activity. But during this period of high activity cancer in these parts is of great rarity. This fact ought to teach us that "unexplained uterine bleeding," an expression that sounds far more formidable than is justified by the condition itself, cannot be accepted as even presumptive evidence of the presence of cancer. When the uterus becomes the seat of a veritable whirlpool of blood (during the later months of gestation) cancer does not attack it. Unexplained bleeding, arising from any source, may justly cause more or less anxiety, depending upon many modifying factors, but as cancer, even when notable for a vast wastage of tissues through sloughing, seldom gives rise to serious bleeding, it is absurd to suppose that active bleeding would signalize the presence of a recent cancer not yet more definitely characterized by other clinical symptoms. Dangerous and even fatal bleeding does, of course, spring from cancerous growths at times, but such cases are of extreme rarity, and when they do arise the fatal character of the condition is apparent to all eyes, unskilled as well as skilled. I have known of numerous cases of uterine bleeding in which cancer had no part and for which no precise cause could ever be assigned. Without meaning to quibble, perhaps I ought to say for which no cause *was* ever assigned, for I must say that many of my so-called investigations have been of so crude a character that they are entitled to a very low degree of respect. Highly equipped laboratories with skillful attendants are not too plentiful, and when the question of cancer has been decided in the negative the investigation has generally been dropped. On the other hand, some women bleed from the womb about as they bleed from the nose, and the microscope must be supposed to be as useless in some cases of metrorrhagia as it is generally in cases of epistaxis. Some women, without being so-called "bleeders," certainly bleed a great deal more than appears to be required by the necessities of the natural menstrual flood, and no one, so far as I know, has ever been able to draw a precise dividing line between menstruation and hemorrhage. "Flooding," as it is sometimes called, is as common with some vigorous women as the appearance of a new moon, but that such women are more liable to invasion from cancer than women with scanty menstruation is an utterly groundless supposition.

Uterine pain, if not due to "a thousand causes," is due at least to a respectable number; and if due to an early cancer, as might be possible, would lead to nothing positive in diagnosis unless corroborated by evidence of a more dependable character. Pain of more or less severity is always an accompaniment of cancer in its later stages, and it may even become unbearable, but pain of such intensity indicates all too plainly that the day for curative operative interference has long since passed. Prolonged pain within defined limits is always a symptom of serious import, but pain of this type is not characteristic of early cancer. It is claimed by some that the uterus may be the seat of intractable neuralgia, without distinguishing pathological alterations of tissue. Granted that this were so, any such case should be examined with the mind fixed upon some hidden constitutional taint or perhaps some latent miasm. Not that I think that an unwarranted hysterectomy is any more culpable than any other unwarranted operative procedure of equal magnitude, but for the reason that no operation of any character whatever ought to be undertaken without the most complete surgical justification. Operations performed for diagnostic purposes are fully warranted in many instances; they ought, indeed, to be performed much more frequently than they are; but such procedures, carried out in the full light of day, and with the whole-hearted approval of all concerned, are eminently within the domain of legitimate surgery and must not be confounded with adventurous exploits that are undertaken upon whimsical impulses and not upon sound surgical grounds. A deeply reddened uterine cervix cannot be justified upon sound physiological principles, but it is no more indicative of underlying cancer than a chronic limp always indicates rheumatism. Localized inflammation may occasionally be of such violent character that the mucous membrane of the cervix is partially destroyed, resembling in fact true ulceration at times, but such conditions generally yield to proper medical treatment, whereas no medicine whatever has the slightest curative effect upon the course of cancer. And it ought to be observed in this connection that no known form of imposture surpasses in depravity that which pretends to alleviate or cure cancer by the internal administration of medicines. It must be acknowledged that many honest men have been misled by this sort of folly, but as a general rule it has sprung from the minds of rapacious upstarts and shameless swindlers.

Wedges of scar tissue imbedded in the walls of the uterus, so familiar to the eye and the exploring finger, cannot be regarded as free from certain powers of mischief, but it must be borne in mind that cancer springs from glandular and not from fibrous tissue. An imperfectly healed laceration of the cervix is far more likely to cause subsequent trouble than any mere area of cicatricial tissue. In a former paper (MEDICAL RECORD, April 13, 1918) I took the ground that if a section of scar tissue gave such trouble as to demand its removal the whole scar must be removed, even if the procedure required of necessity the taking away of the uterus itself. This leads me to say again that many more operations ought to be undertaken for purposes of diagnosis and carried to completion according to the conditions revealed by the pathology present.

Irritating discharges, sometimes of a pronounced fetid character, must be attributed to some of the more familiar forms of infection, and cannot of themselves be accepted as forerunners of malignancy. The proper line of treatment must, of course, be determined in any case by the facts presented in evidence, but something far more convincing than suspicion is demanded before the undertaking of any serious surgical procedure. Nor must it be understood that serious and possibly irreparable mischief may not be inflicted without the employment of cutting instruments. I have known some deplorable results to follow the senseless and reckless manipulations of mammary growths by the disciples of a Western mechanical cult whose dangerous performances in the realm of infectious diseases have most happily brought their pretensions almost to the point of extinction.

The subject of uterine cancer is one of such immense importance that it should be studied with untiring thought and energy. Every fact connected with its progress, every rational theory honestly set forth concerning its various phenomena, ought to be analyzed with the most scrupulous care and subjected to the most searching methods of investigation. One thing ought to be borne in mind as fundamental: that which is merely insoluble cannot be of miraculous origin under any conditions, and the only progress possible within this field of study will be found to lie clearly within the limits of pure scientific research. An analysis of the renowned labors of Pasteur, Koch, and Lister ought to serve as a warning to those who dissipate their energies in the pursuit of whimsical fancies.

Certain facts connected with uterine cancer are so well established that some fair and practical inferences may, I believe, be drawn from them. Uterine cancer begins in the cervix. Comparatively speaking, it is of slow growth. The cervical canal is lined with flat epithelium, which extends outward to the rim of the organ and blends gradually with the mucous lining of the vaginal outlet. Cancers of the cervix probably begin in the mucous coat and extend thence to the lymphatics of the neck, eventually involving the deeper pelvic lymphatics, where secondary manifestations are so often found, unless the progress of the growth has been happily arrested by rational surgical interference. If the same condition should appear on the cheek or the nose it would be known as a "skin cancer," a growth of such sluggish development as to give rise to serious doubts involving its real malignant nature. The uterine neck, composed largely of atrophied tissues and covered with cells whose histological character supplies the necessary elements for growth, affords a most inviting field for the invasion of malignant developments.

Pseudo-ulceration is not infreqent in this region, and its presence may, on hasty examination, be mistaken for true ulceration or cancer. While it is important not to confound the simpler with the graver condition, it is more important still to treat every such case, in some respects, precisely as if cancer were known to be present. Under no circumstances must the cervix be punctured with a tenaculum, or approached with any sharp instrument whatever during the period of doubt. Most fortunately pseudo-ulceration yields generally with decisive

promptness to mild local applications. Peruvian balsam, a mixture of iodine with glycerin, some of the milder silver salts in solution, and a dry dressing composed of equal parts of boric and salicylic acids, are perhaps as efficacious as any remedies that we have at our command. The vaginal canal may be washed out several times a day with solutions of common salt or of potassium permanganate. All chemical irritation must be avoided. Cancer yields to none of these medicines. Pseudo-ulceration does. The diagnosis is thus made clear, generally within a few days. In any case of doubt the condition may be accepted as cancerous and no further delay can be justified in operating.

From the present state of our knowledge concerning cancer I believe the following conclusions to be warranted:

That cancer is of *spontaneous origin*.

That it arises in obedience to certain forces of decay, the real nature of which we know nothing.

That heredity, prolonged localized irritation, and constitutional taint must in some degree be acknowledged as occasional contributing factors.

That it is marked by two stages, one of development or growth, and one of decline or disintegration.

That it begins always in a localized area and during its period of development gives rise to no conclusive symptoms that indicate its malignant character.

That the gross dimensions of a cancerous growth bear no definite relation to its degree of malignancy nor of themselves alone indicate in any manner the nearness or remoteness of its disintegration.

That the disease always progresses toward a fatal ending unless arrested by some device of the surgical art.

That if wholly eradicated during its period of growth, before its period of decay has begun, its powers for mischief are ended.

CHRONIC OBSCURE FEVER IN CHILDREN.

By J. EPSTEIN, M.D.,

NEW YORK.

A RISE in the thermometer index is usually the first evidence of some serious abnormality in the processes of the human organism. By means of inspection, palpation, percussion, auscultation, and reasoning, the cause of the fever is ascertained and deviations from the normal workings of the body are interpreted, classified, and diagnosed. As an aid to a correct diagnosis the history of the patient and the laboratory findings are of great importance. In infants and young children, a rise in the temperature is frequently the only evidence of some pathological process. The fever may be prolonged, insidious, remittent, or intermittent, and for days or weeks the symptoms and signs may be ill defined, atypical, and uncertain. The young child cannot express intelligently his feelings of pain and discomfort, and the laboratory may not be available or helpful. Having only the rise in the temperature as the sole evidence of some diseased process, a diagnosis is frequently difficult to make. A knowledge of the various possibilities which may be the cause of the chronic fever will lead to further observation and study and finally to the proper diagnosis. The following are some of the diseases which cause a protracted fever in children without sufficient physical signs.

Sepsis.—Septic infection is not an uncommon cause of obscure fever in infants and children. It is the most important cause of fever in the newborn. A continuous, irregular fever, occurring at this period of life is, in the majority of instances, due to sepsis. The principal primary focus of infection is usually the umbilicus, though any other part of the body may be the portal of entry for various pathogenic organisms. A diagnosis of septicemia in infants and children is occasionally difficult to make, and is frequently not thought of at all. A septic child looks ill, prostrated, and sallow, loses weight, sweats a great deal, and has a protracted, irregular fever, with no physical signs to account for it. A blood examination will show a high leucocytosis, and a blood culture will demonstrate both the infection and the infecting organism. A petechial rash, with ecchymotic spots scattered all over the body, is not infrequent in septic infection. Later in the course of the disease there may be a general arthritis, meningitis, endocarditis, or peritonitis. In all cases of sepsis an effort should be made to trace the infection to its source. Any cavity or sinus of the body may be a nidus for infection.

Influenza.—Subacute or chronic influenza in childhood may run a protracted course with few symptoms and no signs. There is an irregular, widely fluctuating temperature, with variable clinical manifestations and no definite physical signs. The child looks ill at the height of the fever, but is bright and happy with each fall of the temperature. Since the persistent temperature is the only or chief symptom of chronic influenza, a diagnosis is frequently difficult to make. The striking features of this disease are the chronicity, the widely oscillating temperature, with varying symptoms, and no signs in a child who appears neither very sick nor entirely well. A blood examination will show a slight leucocytosis, and, when possible, the *Bacillus influenzæ*, or Pfeiffer's bacillus, may be isolated from the bronchial secretions.

Malaria.—Malarial fever in infants and young children differs markedly from that in older children and adults. The typical clinical manifestations of a regular intermittent fever with an orderly succession of a cold, hot, and wet stage are not present in the very young. There may be a prolonged, remittent or irregular fever, with a variety of symptoms which point to no particular disease. The striking malarial shaking chill is frequently replaced in the young child by chilly sensations, cold extremities, cyanosis, prostration, and occasionally convulsions. There may be vomiting, headache, general aches and pains, and sometimes pulmonary congestion leading to a mistaken diagnosis of pneumonia. The fever is usually high, continues for several hours, then subsides, to be repeated again. The wet or sweating stage is either very slight or entirely absent. The spleen, though usually large, is in itself not diagnostic of malaria, because a palpable or an enlarged spleen is not infrequent in children, especially in anemia, rickets, congenital syphilis, and chronic intestinal intoxications. Since the typical group of symptoms which are diagnostic of

malaria in later life are not present in the young, a diagnosis should be based mainly on the periodic occurrence of fever, together with chilly sensations. A palpable spleen, headache, gastric disturbances, and other indefinite symptoms and signs may be present. An examination of the blood for malarial organisms should be made in every case of periodic fever, and even if this is negative, quinine should be given for its diagnostic and therapeutic tests. A careful history will always aid in the diagnosis, as in the following case.

A girl three years old, who was never out of the city, was brought to me because of frequent attacks of fever. For weeks before the child came under my care, she was treated for this fever and a variety of diagnoses were made, including chronic tonsillar infection, for which the removal of a pair of innocent looking tonsils was advised. On questioning the mother I elicited the fact that on certain days, at almost the same time, the child complained of feeling ill and chilly, which lasted for a few hours and then subsided, leaving her as well as ever until the next attack. This periodic illness with fever and chilliness at once suggested the diagnosis of malaria and a blood examination proved its correctness.

Pyelitis.—This disease is characterized by a subacute or chronic malaria-like fever, and unless the urine is repeatedly examined a diagnosis is difficult to make. The urine, the blood, and the ears constitute a triad which should always be examined in obscure fevers in early life. Pyelitis in infancy and childhood may be acute, with a high fluctuating fever, chills, prostration, and gastrointestinal disturbance. In the majority of cases the disease runs a protracted course, with a moderate intermittent fever, slight chilly sensations, poor appetite, and loss in weight, with no physical signs. Older children may complain of pain in the abdomen or along the kidney region. In some children there is nothing but a slight, obscure, chronic fever, with no other evidence of disease. In all cases of alternate febrile and afebrile periods or a prolonged subacute fever the urine should be examined for evidence of pyelitis.

Endocarditis.—In its early stage, rheumatic endocarditis is a disease of symptoms and no signs. Anatomical valvular changes which lead to incompetency or stenosis probably occur after a prolonged, indefinite cardiorheumatic illness, during which time the valves maintain their functional integrity and there are no physical signs of endocardial disease. When a diagnosis of endocarditis is made on a dilated heart with a murmuring sound which tells of valvular destruction, it is usually too late for permanent repair. The time to diagnose and treat rheumatic endocarditis is in the prevalvular stage. A diagnosis at this early period of endocardial disease is, of course, difficult to make, but certain symptoms may lead to further observation, careful examination, and a correct diagnosis. A persistent, obscure afternoon rise in temperature in a child over five years of age who complains of an occasional sore throat, a stiff joint, a dull ache, or slight muscle pain, points to the diagnosis of endocarditis. Repeated examinations of the heart will show a diminished valvular tone, a muffled first sound, and a rapid irregular pulse. Though at this early stage of cardiac disease there are no murmurs or other typical signs of endocarditis, still the obscure afternoon rise in temperature, the joint and muscle aches, and the increased pulse rate, indicate incipient endocarditis. The child should be put to bed on a cardiorheumatic treatment to save the heart from ultimate ruin.

Tuberculosis.—Tuberculosis in infants and young children is primarily a disease of fever and failing nutrition. The onset is insidious and indefinite. For weeks the child may have a slight fever, which is often not noticed at all, or there may be a higher fever with no symptoms or signs to account for it. Later there is a gradual loss of weight and strength, the child becomes anemic, asthenic, and wasted, for which there is no apparent reason. It is during this stage of the disease, when there is nothing else but an obscure, protracted fever and failing nutrition to indicate a chronic diseased process, that a correct diagnosis becomes of the utmost importance.

Little or nothing can be done for the child when the tuberculous process becomes localized in the lungs, brain, or any other vital organ of the body. Continuous loss of weight in a child with a chronic fever means tuberculosis in the majority of cases. The Von Pirquet test will aid in the diagnosis, and should be applied in all cases of obscure fever with loss in weight and strength.

Blood Diseases.—In pernicious anemia, splenic anemia, pseudoleucemic anemia, leucemia, and Hodgkins' disease, an irregular chronic fever may be the first evidence of disease. Long before there are definite signs and symptoms of the pathogenesis of the blood or the hematopoietic system there is a protracted rise of temperature. In all children with a blanched skin, asthenia, shortness of breath, and a hemic murmur, together with an obscure fever, an examination of the blood should be made for a correct hematological diagnosis. Later in the course of the disease there may be purpuric spots, hemorrhages from different parts of the body, enlargement of the superficial and deep lymphatic glands and the spleen.

Nasopharyngo-Tonsillar Infections.—The nasopharynx, pharynx, and tonsils form the boundaries of the main entrance to the internal organs of the body. There are many recesses and crevices along its course, and, being supplied with air, food, heat, and moisture, it forms an ideal breeding place for pathogenic organisms. Subacute and chronic infection in the nasopharyngo-tonsillar area is not infrequent, and in cases of obscure chronic fever this hidden space should be carefully explored. Oral sepsis due to carious teeth of the deciduous or permanent set is a frequent source of local or general infections and an important cause of chronic obscure fever in children.

222 East Broadway.

Ozena as a Result of Gassing.—The mysterious nature of ozena is by no means cleared up by the observation that typical cases have followed exposure to poison gas. Matier calls this type of affection traumatic ozena. The patient whose case is described was in a bad general condition and also presented severe pulmonary complications as a result of gassing. Matier does not attribute the nasal condition to the local insult but to the bad general condition; according to his own experience all ozena patients are in poor physical condition.—*Revue de Laryngologie.*

OCCUPATION FOR TUBERCULOUS PATIENTS.

By MOSES KAHN, M.D.,

BROOKLYN, N. Y.

VISITING PHYSICIAN TO ST. ANTHONY'S TUBERCULOSIS HOSPITAL, WOODHAVEN, N. Y.

WHEN the patient first comes under the care of the physician, absolute rest in bed for a week or two is best. If there are signs of active disease, such as much cough, elevated temperature, pain, and signs of activity, as shown by physical examination of the chest, such as moist râles, the patient is kept at rest, lying in the open air.

When these signs of active disease are gone then slowly increased walking exercises should be started. A good method is to prescribe fifteen minutes' easy walking in the morning and fifteen minutes' walking in the afternoon. In cold weather the walks should be taken at such hours in the day as the sun is strong. In hot weather the walks are taken at other times when the sun is least strong. During this time the pulse and symptoms are noted daily. If the patient stands this walk well for two weeks, as shown by no untoward symptoms or physical signs, the walk is then increased to 30 minutes each morning and afternoon.

At the end of two more weeks, if the subjective symptoms and physical signs show the disease is tending toward arrest, instead of increasing the time of walk, we substitute some useful work. Useful work prevents morbid introspection, passes the time quickly for the patient, increases his appetite and strength, and develops his muscles or brain.

Patients idle for long periods get depressed, irritable, weak, and are afraid to work when healed. We must gradually increase the amount of work every two weeks so that by the end of the period of treatment the patient will have reached a full day's work and he will then be ready to return to his old occupation.

The method of complete rest for six months or longer, and then stepping right into a full day's work is very bad. The patient is soft and flabby, and often easily relapses.

The question always arises when the disease is arrested, "Doctor, what work can I do, now that I am well?" The best authorities in tuberculosis all agree now that as a general rule a return to the old occupation is the best. The only exceptions to this rule are where the old occupations are very unhealthy or very laborious.

The old occupation is best because the patient has trained himself for years in it. It would be a great hardship to learn a new occupation. He knows the old trade best, makes good wages at it, and could easiest fall back at it. It took him many years to become proficient at it. Outdoor occupations are best, but are not always available. Indoor occupations will do.

Patients with arrested or apparently cured tuberculosis must be very careful for the rest of their lives to avoid a relapse. They should get an abundance of rest and sleep, keep windows open day and night. They should avoid all alcohol. They should avoid smoking, or, at least, smoke only very little.

Tuberculosis patients should, if possible, take a vacation in the summer. Rest on a quiet farm is best.

When a person with arrested or apparently cured tuberculosis develops a cold or does not feel well, he should stay home and go to bed and rest up till he is perfectly well. By so doing he may avoid a relapse.

Above all, these persons should always go slowly, never over work, never hurry. They should ever remember never to try to complete or imitate the strenuous methods of well persons in business or pleasure. By so doing many of my old patients have remained well and in business for many years.

702-A HALSEY STREET.

Medicolegal Notes.

Use of X-Rays Curatively.—The Virginia Court of Appeals holds that the failure of a physician to warn a patient of the danger of possible bad consequences of using a remedy is not negligence per se. But where a physician not only fails to warn of dangers of a certain treatment, but gives positive assurance of a cure thereby, he is liable for harmful consequences of the treatment where, if such warning had been given, the patient would not have taken the treatment. One of the counts in an action for malpractice by the negligent diagnosis and treatment of eczema of the plaintiff's legs and ankles alleged that the plaintiff consulted the defendant as a physician regarding eczema and as to the proper treatment thereof, that the defendant well knew, or by the exercise of ordinary skill and forethought should have known, of the danger of such treatment, that notwithstanding the defendant misled the plaintiff by not only not giving him warning as to the possible bad consequences, but by affirmatively assuring him that if the defendant applied the *x*-ray treatment to the plaintiff's legs and ankles his eczema would be cured and his legs would be well in eight weeks, and that, had the defendant given the plaintiff warning aforesaid, the latter would not have submitted to the treatment, was in tort and not in contract.

In addition to expert testimony in behalf of both the plaintiff and the defendant on the question of what was the standard of professional skill and care by which the competency and conduct of the defendant physician in giving *x*-ray treatment should be measured, the result of the treatment was properly to be considered by the jury. Since the standards of professional care and skill of the defendant physician involved the highly specialized art of treatment of the plaintiff by *x*-rays, expert testimony fixing such standards was essential to support a verdict for the plaintiff. As to the general professional standard of skill and care, the plaintiff introduced one expert witness only. The evidence, without conflict, showed that this witness was a general practitioner of exceptionally high standing in the profession; that he had used the *x*-ray to take photographs; that he had never used the *x*-ray curatively, but had had personal experience and knowledge of ulcers caused by *x*-rays, and from his professional training and reading of scientific books treating of *x*-rays and the results of their curative use, had a certain degree of knowledge on the subject of the proper use of *x*-rays, which he disclosed to the jury. He expressly declined to testify as an expert upon the subject of the mechanical standard. The court held that his testimony was admissable on the former subject, and that its credibility and weight were for the jury.

The jury by their verdict having found upon conflicting evidence that the plaintiff's injury was caused by *x*-rays, the finding was held conclusive.—Hunter v. Burroughs, Virginia Supreme Court of Appeals, 96 S.E. 360.

Military Medicine.

Night Blindness in War.—Nyctalopia has been ascribed to various causes, but acute night blindness has been generally associated with defective nutrition such as scurvy, malaria, nephritis, jaundice, and anemia due to poor diet. Donald Gunn, quoted by Johnston Smith in Allbutt's "System of Medicine," does not accept this view, but holds that the defect depends primarily on exhaustion of the retina from prolonged exposure to bright light, although he admits that any cause which lowers the general vitality will tend to favor the incapacity of the retina to respond to less than the strongest stimuli. F. Best (*Muench. med. Woch.*, August 17, 1915) examined 36 cases of night blindness discovered among the troops at the front. The 36 cases were divided as follows: (1) Those due to disturbances of the liver following injury by shrapnel; (2) congenital cases; (3) nyctalopia due to errors of refraction. Two-thirds of all the cases were of this type; (4) hysterical forms; (5) cases following sun blinding; (6) those following night service in the trenches; (7) nyctalopia due to hunger and emaciation, either with or without areas of xerosis. In the *American Journal of Ophthalmology* for July, 1918, Dr. Marcel Davis of Brussels, gives an exhaustive account of cases of night blindness which have come under notice during a period of 29 months. Of 2,700 patients who presented themselves during that time 203 complained of not seeing at night. Most of these men were from the ranks, only two being officers. The 203 cases were divided as follows as regards refraction: Emmetropes 66, two having corneal scars; hyperopes less than 1 D., 14; hyperopes 1 D. and more, 50, of whom one had corneal scars; astigmic hyperopes, 20, one with lenticular opacities; myopes, 31, two cases of retinitis pigmentosa; astigmic myopes, 16; having mixed astigmia, 4. Of course, the cases had to be closely investigated to preclude the possibility of malingering. Among 27 cases regarding which responses were obtained from the commandants of the companies, the diagnosis was confirmed in 18 cases, 9 being clearly chargeable to simulation. Thirteen other simulators were detected and it is probable that some were passed undetected.

Among 86 men questioned as to when the affection first manifested itself, 23 claimed to have been attacked before the war, while 63 had done satisfactory night service during a part of the campaign, and had been attacked subsequently. Davis believes the nyctalopes examined by him can be classed in the following manner: (1) Nyctalopia with retinal lesions; (2) nyctalopia of congenital origin; (3) optical nyctalopia, by errors of refraction uncorrected, by clouding of the media; (4) nyctalopia, without lesions. Irue suggests as an explanation of congenital night blindness a deficiency in the rods or in the visual purple, and thinks that congenital night blindness may have passed unperceived in soldiers who were affected. It required actual night duty to reveal their defect. The man with myopic vision as well as the man with uncorrected astigmatism, having an inferior visual acuity by day obviously cannot see so well as the man with normal vision by night. Davis points out that Landolt recognizes several causes of nyctalopia in corrected myopes. (1) With equal pupils in the corrected myope the retinal image is less brilliant than in the emmetrope; (2) wearing of correcting glasses renders the image more clear but less luminous; the correcting glass reflects a part of the light and the point of reflection interferes with the sight; (3) the light at night furnishes a predominance of blue rays, the most refrangible, which give a focus more in front of the retina than do the other radiations; (4) a last cause, indicated by Magitot also, is the effect of elongation of the myopic eye on the ocular membranes, and particularly on the vessels and pigment epithelium. In the nyctalope without lesions, but with an error of refraction corrected, Landolt has never met with hyperopia. Davis and colleagues, on the contrary, have encountered a large number of hyperopes. As to the general causes of this condition Davis and coworkers do not regard its production, so far as the Belgian soldiers are concerned, as due to dietetic defects. They are well fed, and though their meals are lacking in fresh vegetables during most of the campaign they have potatoes daily at one meal. The coffee, which is their customary beverage, is not strong enough to be toxic. Alcohol is prohibited on the Belgian front. They are enormous smokers, but tobacco ambylopia never produces night blindness. Moreover, with respect to malnutrition as a probable cause of the affection among the Belgian soldiers, Davis states that he has never found spots of xerosis on the conjunctiva which frequently accompany nyctalopia originating from malnutrition or cachexia. Davis concludes, as the result of his and his colleagues' investigations, that war conditions in themselves are responsible for most of the night blindness in soldiers. Physical strain, violent emotional disturbances, and severe fatigue are reflected in the function of the heart muscle. Temporary disturbances of circulation caused by cardiac fatigue cannot fail to be represented in the functioning of the choriocapillaris, affecting the delicate pigment epithelium of the retina and the secretion of the visual purple. The point is emphasized that night blindness belongs almost exclusively to the foot soldier. He is subjected to intense fatigue as well as to the most violent emotions and lack of sleep, whereby the cardiac fatigue is increased. That these are potent causes appears to be substantiated by the fact that in the worst sectors, where the causes of fatigue and emotion are most in evidence, the number of cases of true nyctalopia are most numerous. Therefore Davis agrees with Weekers (*Archives d'Ophthalmologie*, v. 35, 1916) that overwork and nervous exhaustion are the real factors in night blindness, but the first named is led to believe that the immediate exciting cause is circulatory disturbance of the choriocapillaris. For treatment, the exact correction of errors of refraction, attention to the underlying condition, and treatment of conjunctivitis and keratitis, which often accompany nyctalopia are indicated. In addition, cod liver oil or calcium lactate should be given. Arsenic, iron, and strychnine also sometimes give encouraging results, and

in some cases simple rest for several days may have the desired effect.

Treatment of Fracture in Warfare.—Sir Arbuthnot Lane, writing in *The Practitioner* for October, 1918, formulates the following conclusions regarding the operative treatment of these injuries:

1. Only in very exceptional circumstances is it advisable to fix fragments of broken bones together by means of plates and screws while the wound is foul.

2. If, for certain reasons, such a procedure is deemed necessary, screws should not be inserted near the broken extremities, but as far from the seat of fracture as possible.

3. It is advisable to postpone operative interference till the wounds have healed for some considerable time and until the tissues are, in all probability, free of organisms. This can usually be determined with reasonable certainty.

4. If any apparently septic focus is observed during an operation, a culture and a vaccine should be obtained from it, and employed at once should symptoms of infection of the wound develop.

5. Should there be any definite suspicion of the presence of latent sepsis, irrigation by Carrel's or similar method must be adopted at once. If not, the wound should be closed completely at the time of operation.

6. Every attempt should be made to avoid any shortening of the limb, or to reduce it to a minimum.

7. The apposition of the whole areas of the broken ends is not necessary, since the interval will fill up subsequently by bone if suitable means are adopted. Fragments of bone or callus should be saved and employed to fill any interval between the pieces of the shaft.

8. Much heavier steel plates are required in this class of case than are usually employed in the less comminuted fractures of civil life. It is most important that the muscles and joints, which are in relation with the fractured bone, shall be moved voluntarily by the patient as soon as possible after the operation, in order to avoid that stiffness and limitation of movement that so often complicate these fractures. This is especially the case in the joints of the knee, ankle, and foot. In order to obviate this trouble, without risking the security of the junction, the plates which are employed to retain the fragments in position must be as long and as strong as circumstances will permit. They should be secured by as many screws as possible. The plates that are often employed are quite inadequate for the purpose. It is obvious that such early treatment cannot be adopted when the fragments are very fragile and the grip of the plate and screws insecure.

9. Providing no strain shall be exerted on the junction likely to develop non-union, the sooner the patient who has been operated on for fracture of one or more long bones of the leg is got up and about, the more bone will be deposited and the more rapid will be the repair at the seat of fracture. For this purpose a good ambulatory splint is a necessity in certain cases.

10. Should the interval between the fragments be so considerable that union is not likely to take place, even after prolonged congestion, brought about by the use of an ambulatory splint, the fragments should be secured in perfect alignment by a plate fixed vertically behind the center of the shaft. When this has been done a portion of one of the fragments, which is usually equal in thickness to a third of the total circumference of the shaft, can be sawed and chiseled off and secured over the interval between the fragments, any piece of bone removed to accommodate the graft in the other fragment being fitted to occupy such existing interval as may be left between the bones. If enough material cannot be obtained from the fractured bone to make a graft, it must be got from some other bone.

11. Most of the failures of bone grafting for extensive loss of substance are due to the surgeon depending on the unsatisfactory grip which the graft alone can be made to exert upon the fragments of the shaft. The essence of success depends on the absolute immobilization of the fragments of the shaft on one another, and of the graft upon those fragments. It is obviously ridiculous to attempt to retain the fragments of bone in a useful position by bone grafts alone in these compound fractures produced by projectiles, as it is in any fracture in which the material securing the fragments in position has to bear considerable strain. In grafting bone into gaps in the lower jaw, fixation is supplemented by interdental splints which lock the jaws.

12. Much has been written about wire screws and plates acting as foreign bodies if used in simple fractures, and producing a rarefying ostitis around them. Should such rarefying ostitis exist, it is undeniable evidence that the technique of the operator is faulty and not the procedure. The remedy is in the hands of the surgeon, who must improve his methods. Frequent failures in unskilled hands have led many to attribute their want of success to the employment of steel plates and screws, and to attempt to avoid sepsis by using other and much less effective means.

13. While the operative treatment of compound fractures produced by projectiles is the most important of all surgical procedures in warfare, it is, perhaps, well to remember that it may demand a degree of asepsis, mechanical skill, resource and judgment in excess of that required for other operations for war conditions.

14. Besides that of sepsis, usually introduced from without, though occasionally developed from a latent infection, hemorrhage is the chief risk which is associated with these operations. This can be best avoided by the use of very powerful hemostatic forceps, which are left in position in the wound for as long as possible during the course of the operation. A ligature is rarely required. It is most important that the wound should be left as dry as possible. When much oozing is expected to follow the operation, a long drainage tube may be left in the wound for twenty-four hours, and so arranged that the extravasated blood may be carried free of the dressings. The removal of the tube does not necessitate any change of dressings, for they are not moistened by the blood.

As to the relative advantage of a stiff and a flail joint, Lane says that in the case of the knee joint when much bone has been carried away the surgeon is apt to argue that if he cannot obtain bony ankylosis between the femurs and tibia he should amputate the limb, in the belief that an artificial limb will afford the patient the best mode of progression. A rigid limb gives the possessor security at the cost of convenience. If the patient is left with a flail joint he can, by wearing an external support, transmit his weight from the pelvis and thigh to the boot. The presence of a ring catch-joint enables him to fix the leg in the situation of the knee joint with great facility and rapidity, while the moment the erect posture is assumed the joint locks and the limb becomes for all practical purposes a rigid one. In such a limb security is sacrificed to convenience. The man cannot do the same amount of heavy work that one with a rigid leg can do, but he is more fitted to lead a conventional town life with comfort to himself and convenience to his fellows.

In dealing with these injuries the surgeon should therefore be influenced by the circumstances of the patient in deciding as to the relative advantage of security and convenience in each individual case. Again, while assuming that a rigid limb is much more useful to the laborer than is any form of artificial limb for an amputation through the thigh, the relative merits of a flail limb and of an artificial leg call for our careful consideration.

Apart from the sentimental value which appertains to the possession of one's own leg, inquiry made among a large number of those who had sustained an amputation through the thigh showed that while a good many continued to wear their artificial limbs with comfort and satisfaction, quite a considerable proportion discarded them altogether, or wore them only for intervals of time, or on occasions. Many of them realized that an amputation entailed numerous discomforts and disadvantages that surgeons generally were not familiar with, but which were very real to the possessor of the stump.

There is a great deal to be said for the advantages which the flail joint in the leg affords. While it is the undisputed intention of the surgeon to obtain a rigid limb if the knee joint has to be lost and that failing it an amputation through the thigh should be performed, it would appear that in a large proportion of the community the individual is better off with a flail joint suitably supported by an apparatus than with a rigid limb or with an artificial limb. This is merely an example of the rule: "that which is universally accepted as true is always false."

The same applies in a lesser degree to the shoulder joint. A humerus ankylosed to the scapula at a suitable angle affords security at the cost of convenience. A humerus moving freely on the scapula affords convenience at the cost of security. For this reason, the patient's habits and circumstances should be considered carefully, before any operation necessitated by destruction of the parts about the shoulder joint by projectiles. On comparing the relative advantages of a stiff shoulder with those of a flail joint one may say that the disadvantage of the flail joint is that the process of education of the muscles and the development of a new false joint is very much more tedious than the convalescence of a humerus ankylosed to the scapula, but the general opinion of patients whose life was not a laborious one preponderated largely in favor of the flail joint. They found it more convenient, and every month added to its security and usefulness.

Enteric Fever in the British Army.—The British Army Medical Service has made a remarkable record in the reduction of enteric fever among British troops. Among the millions of British troops engaged only 4,000 cases of enteric fever were reported in four years. This is in striking contrast to the 50,000 cases of that affection among 200,000 men in the two and one-half years of the South African War.

Influenza Plague in the Army Wears Itself Out.—The Surgeon General's weekly report shows that the influenza epidemic in the army is rapidly coming to an end. For the week ended November 8 there were 6,887 cases as compared with 18,175 for the previous week. A marked improvement was also shown in the pneumonia situation.

Elks' War Hospital Dedicated.—The Elks' reconstruction hospital in Boston for the treatment of wounded and disfigured soldiers was dedicated on November 16, and turned over to the Government with impressive ceremonies.

Gifts to the Red Cross.—The Atlantic Division of the American Red Cross will receive $100,000 from the estate of James A. Scrymser. This is the largest single bequest the organization has thus far received. Another gift recently received is an ambulance fully equipped for overseas service from the Brooklyn Navy Yard.

Italy and France Honor Red Cross Men.—Lieut.-Col. Robert R. Perkins and Lieut.-Col. Grayson M. P. Murphy have received the decoration of Commander of the Crown of Italy from the Italian Government. Twelve additional officers of the American Red Cross have also been decorated by the Italian Government. On November 14, the Municipal Council of Paris gave a reception in honor of the American Red Cross at which the French Government was represented.

Nurses Still Needed.—The American Red Cross has sent out a call for 1500 nurses' aids for service in the hospitals of France, women between the ages of 35 and 45 of liberal education and preferably with a college education are desired. An appeal is also made for twenty-five Czecho-Slovak nurses' aids for immediate service overseas. The Red Cross Commission to Greece has arrived in Paris. The Commission includes sixty physicians, nurses, pharmacists, agricultural instructors, and social workers, who will aid the Greek Government in fighting the typhus plague in Mitylene and Janina.

Deaths in the Service.—Lieut. U. F. Bass, M. C., U. S. Army, a colored physician of Fredericksburg, Va., was killed in the latter part of October while dressing wounds of soldiers on the firing line in France. He was a graduate of the Leonard Medical School, North Carolina, in 1906.

PANDEMIC INFLUENZA AND THE WAR.

TROCELLO begins an account of this subject with a quotation from the MEDICAL RECORD, from which it appears that the first intimation appeared in attacks in Sing Sing Prison and Ford's factories in Detroit (*Annali di medicina navale e coloniale*, 1918, July-August). This incidence goes back to March of the present year, and hence antedates any recognized outbreak of influenza in Europe. Moreover, the American episodes were pronounced genuine influenza of the 1889 type. About one month later we find the earliest notices of an influenza-like outbreak in Europe. The first mass incidence occurred in Spain in the latter part of May. The total number attacked in Spain has been computed as 8,000,000. The character of the pandemic was mysterious in the extreme, for hardly two authorities agreed as to its intimate nature. The Spanish bacteriologists and clinicians showed no uniformity, and by the end of June the epidemic was worn out, and with it further opportunities of study, which might have solved the problem. In the meantime, grip-like cases in England seemed for various reasons to be of different nature from the Spanish pandemic, especially in the epidemiology itself. In Germany the first reports were few and scanty, but apparently from the early spring the troops were suffering more or less from grip-like maladies. Statistics, or other exact data, are especially lacking. The earliest cases in France go back to the first days of May, and on the 17th of this month, or before the Spanish outbreak, the disease was pronounced at the Société médicale des hôpitaux to be the influenza of 1889. In France, as in England, there was no pandemic, and the disease seemed, on the whole, benign. The French, like the Spanish bacteriologists, could not throw much light on the malady, but evidence began to accumulate that Pfeiffer's bacillus could not be held entirely responsible. The British troops in France now began to suffer to almost pandemic extent, in mild degree, and without advance of our knowledge. It was now Italy's turn to suffer, beginning in the second half of May. The well-known confusion with three-day fever followed. The sea forces appeared to bear the brunt of the infection, and as the result of great activity among the bacteriologists Pfeiffer's bacillus was installed as the essential cause. The epidemic persisted in the naval forces during June and July. During the summer months England appeared to be severely hit, judging from the great number of articles published in the special journals. A commission was established to investigate the cause and nature of the malady (this had been done already in Germany). Switzerland had a severe siege in June-July, and the complete reports from this compact little country were perhaps the first to show the gravity and peril of the disease.

In Germany the disease received two names, viz., "Flanders grippe" and the "Spanish disease." The whole country, sooner or later, was claimed by the disease. It will be recalled that while grip cases were seen in Germany early in the spring the recrudescence or cumulation of later months was fastened on other countries. Here one may note, in passing, a striking parallelism with the early history of syphilis, the early sparse incidence in one's own country being ignored while the mass incidence was blamed upon a neighbor country. The German bacteriologists showed no greater harmony among themselves than those of other lands. There were here, as elsewhere, Pfeifferites and antis, the latter regarding *B. influenzæ* as no more than a cause of second infection. In practically all of the infected countries new germs have been isolated and described, while in many, if not all, the disease has been thought to be due to a filtrable virus without known morphology or other positive attributes. There is also a difference of opinion as to whether we have to do with a new or old malady, a simple affection with virulence increased by war conditions, or a new and deadly disease which may be masked under different guises. The sifting and weighing of evidence shows plainly that the pandemic is influenza or epidemic grippe. It is assumed, and in part shown, that the disease must have prevailed in Spain long before the general outbreak in that land. Present in Spain in April, it extended to the neighboring countries, and the various pandemic explosions occurred without special sequence, that in Spain being, naturally, the earliest. Whence did Spain derive the disease? This cannot be answered, but the author feels convinced that the occurrence of early though limited outbreaks in the United States as far back as March, signals out this country as the starting point of the pandemic.

THE EFFECT OF THE VERDICT ON RAILWAY SPINE.

THE time has not yet passed when lawyers regard with suspicion every suit for damages against a corporation. Especially has this been true when the injuries alleged were partly mental and partly insults to the autonomic system. Particularly when it was found that many cases improved remarkably or recovered entirely after receiving a verdict for a fat sum did the sneers become more pronounced and equally divided between the greed of the claimant and the gullibility

or dishonesty of the doctor. Thus it has become almost a universal custom for the corporation's lawyer to ask some such question as "Is it not true, doctor, that a verdict in his favor would probably cure the plaintiff?" Now the question of traumatic neurasthenia, especially that form of it often called "railway spine," has been but little understood in the past, in spite of the excellent descriptions of it given by Oppenheim and Pearce Bailey. That there are fakers who seek to victimize railroads it would be useless to deny and indeed real "railway spine" can be so closely simulated by a clever malingerer that unless the physician is very careful he will be deceived.

We should say, in the first place, that no general practitioner should undertake to pass upon such a case unless he feels that he is very well versed in neurology. Otherwise he will run the risk of making a mistake which will expose him, at the best, to ridicule, and at the worst, to suspicion. For traumatic neurasthenia, besides the subjective symptoms (which are ruled out in court as being hearsay evidence), presents a well-defined picture of objective symptoms which a trained neurologist can elicit without a great deal of trouble. With a little care, the malingerer, no matter how artful, can be eliminated.* There then remains a class of honest sufferers whose psychology we should investigate a little before we sneer at "miraculous recoveries."

We have in mind a woman patient injured in a railroad wreck and unable to walk who was examined by a dozen neurologists and general practitioners. The former found traumatic neurasthenia; the latter nothing. She received a verdict of $50,000. Whereupon she of course got well? Nothing of the kind. She continued to be disabled for two years during which she made the round of specialists. Finally a psuedo-operation was done and she recovered. Why? Because, according to the prevailing theory, her unconscious would not permit her to recover simply because she received so much money, but forced her to undergo an operation for self-justification.

Perhaps in this case the woman received too much money. But on the other hand there are those who think themselves entitled to ten or twenty thousand dollars and who receive a verdict for one thousand. Such treatment is to them an insult and intensifies their hate of the corporation, which represents to them autocracy, greed, and oppression—a hate which is, by the way, probably back of a great many of these cases of railway spine. Can we expect such a person to recover? No, and he doesn't, or at least not until a long time afterward.

So that a verdict is not the main thing after all, and a "miraculous recovery" immediately after the damages have been paid should give rise to the suspicion that it was not a true case of traumatic neurasthenia.

*See "Malingering," by A. B. Jones and L. J. Llewellyn. Philadelphia: P. Blakiston's Son & Company, 1917.

ANECDOTAL MEDICINE AND ITS NEGLECT.

THE phenomena of a "popular" malady can at times be indicated by anecdotes which visualize it far better than the staid textbook accounts of the disease; and while anecdotal medicine is not suited for curriculum study and quizzing and examination, it is or should be of value as a *hors d'œuvre*, so to speak, in the medical student menu. This Socratic or man-to-man method could be shown up favorably in the case of a charlatan who was forced to take the dreaded State Board Examination, and was preparing for the ordeal in a rural medical college. He heard the surgeon emphasize the difficulties of diagnosis between recent fracture and sprain and insist that in such a dilemma it was playing safe to diagnosticate fracture. He reacted with the query, "in such a case, Professor, would you *charge* for a fracture or for a sprain?" It was only too evident that the future legally qualified practitioner had studied the fee table in advance of the works specified in the curriculum, and had learned that while the fee for sprain was limited to a beggarly five dollars the reward for treating fracture varied from twenty-five dollars up to the utmost the traffic would stand. The class saw the humor of the situation, but it is to be feared that the teacher was handicapped in this regard, and was thrown off his mental equipoise entirely by the crudity of his listener.

But let us select under the caption "anecdotal medicine" something definite like the psyche in typhoid fever. We know of course that these patients must, etymologically, be "stupid," and we know, perhaps from experience, that at times they are violently delirious and try to jump out of the window. We realize to a much less degree that there are subtle nuances of mental behavior that deceive the majority, if not the elect. In passing we may remark that we have seen a victim of manic-depressive insanity in the manic phase antagonize repeatedly an entire medical society who beheld in his peculiar behavior only pure "cussedness" or eccentricity or desire to attract attention, or any other motive, except the true one that he was insane in the utmost degree. A similar sort of behavior is seen frequently in ordinary typhoid, as anecdotal medicine can readily show.

In the first example a student in a small town contracted typhoid in the ambulant form and his taking his bed was not known for several days. His friends, when they first heard of his misfortune, descended upon him in a body, all prepared to do everything possible for him. Unfortunately, perhaps with the idea of preventing contagion, all of them entered the room smoking. The sick youth, who seemed preternaturally sane, resented the smoking bitterly as a badge of disrespect and turned his face incontinently to the wall. His friends, seeing in him otherwise only evidences of good balance, resented bitterly this snub and it required much explanation on both

sides to adjudicate the matter to the satisfaction of all parties. Naturally the amende was deferred until recovery.

Such a case is by no means exceptional. In a similar example there was an unusual comedy element. The sick man, also a student, happened to be living under an alias—that is he had changed his name (or perhaps his father before him had done this) because of some real or fancied racial or other handicap. It chanced that one visitor to the bedside was the only partaker in the secret. He was for some unknown reason received in a cavalier fashion, the sick man turning to the wall on the entrance of the usually welcome friend. As the victim was said to have been entirely rational, having seen other callers during the day, the late comer was so enraged that he let escape him the secret of the man's birth. No harm resulted, because the sick man was popular and his friends treated the disclosure slightingly.

In a third case a young student who afterward became illustrious was overtaken with typhoid in a small community. He was naturally of a kindly and humane disposition, but under the influence of the illness developed an exaggerated ego, not unlike that sometimes attributed to the tuberculous subject. The nurse, to whom he had been personally attached on a health basis, was made to do double duty and was not in the least considered as a human being, much less as a friend. The interne, who had been a friend to both patient and nurse, could not be made to understand that the sick man's behavior was an integral part of the disease and never forgave him for his supposed brutality and callousness. The most striking feature of these cases is the complete ignorance of the untaught physician concerning the pathology of the ego. It is evident that the typhoid subject, while apparently in complete possession of his faculties—which may even appear accentuated by the disease—is still disturbed in both the emotional and intellectual spheres. His ego is augmented, as shown by his sensitiveness and quickness to take offence, and his judgment is dimmed, but perhaps only as a consequence of the preceding.

MICROBIAL FLORA OF THE GRIPPE.

THE polymorphous nature of the germ causes of the present influenza pandemic has already been recognized. At its outset notably benign, the disease has become malevolent in part with its world wide generalization. In some new localities visited it is notably benign, as in certain cities in South America; while in South Africa it is notably severe. In *La Presse Médicale* for October 3, Orticoni, Barbie, and Leclerc, army pathologists, have divided the bacteriology into two types—that of mild grippe and that of severe and complicated grippe. In mild grippe seen early, blood cultures were uniformly sterile. Examination of mucosities and animal experimentation gave results practically negative throughout. The coccobacillus of Pfeiffer was most assuredly absent. Only a few pneumococci of doubtful pathogenicity were found. On the other hand, in the severe type with bronchopneumonia, a germ was in evidence which at least strongly resembled Pfeiffer's. It was cultivated from the blood only after considerable pains, using special media. Its presence was by no means constant. In pleural exudates it seemed to show slight mutation and was always associated with pneumococci and streptococci. Passed into the peritoneal cavity of the guinea pig it was highly pathogenic and showed further pleomorphism. Wherever found in the blood it was almost always in association with pneumococci or germs which closely resembled the latter. In the sputum, on the other hand, Pfeiffer's bacillus was not seen. Here in both pneumonic and non-pneumonic cases the dominant germ was the pneumococcus and a highly pathogenic pneumobacillus was sometimes seen. A striking discovery was the relatively late appearance of the influenza bacillus in cases exhibiting the more familiar pneumococci and streptococci. The question of secondary infection with the former is raised.

In the same journal, for October 17, Vitoux gives an interesting account of a research into the microbiology of the influenza pandemic under animal experiment control. The work was done by Nicolle and Lebailly and the paper was read before the Academy by Roux of the Pasteur Institute. The original experiments had consisted in the inoculation of unfiltered, bronchial secretions into a monkey. The same secretions, filtered, were injected into two human volunteers. In the animal experiment the disease appeared on the sixth day with high fever persisting three days. At the same time the animal lost weight and showed depression. The human subject first inoculated subcutaneously with the filtered secretion developed classical influenza (the duration of incubation is not stated). The other volunteer, who received an intravenous injection of the same type, developed no illness whatever. Later when inoculated with the monkey's blood during the febrile period, this time under his skin, the result was also negative. A second monkey inoculated under the same conditions as the first developed the same picture as the latter save that the incubation period was 5 days. At the same time a man inoculated subcutaneously with filtered virus from the same source developed a mild attack of influenza. Another man proved refractory to an intravenous injection. Both monkeys were inoculated by rubbing the virus into the nasal chambers and injecting it under the conjunctivae. The authors believe that the influenza virus is filterable and cannot be related to known bacilli, that it does not render the blood infectious, and that the source of contagion is the bronchial secretions. The sterile blood shows plainly that insects play no part in its propagation.

Color Music.

Music may be said to be the most universal of the arts; the art which appeals most generally to mankind. During the present war the psychological importance of music has been demonstrated more clearly than ever before and it is now recognized as an essential feature of the soldier's life, both in camp and at the front. It is therefore of particular interest just now to note what may be termed a "new departure" in music; though the idea may not be new, it has never been put to any extensive practical use, and Color Music is still more or less of an unknown quantity. The present note is not concerned with the employment of color in combination with musical compositions—as, for instance, with the "fire music" of Scriabine—but rather with the relation existing between music and color from a psychological point of view; and what we know of the laws of vibration makes it easy to understand the closeness of this relation. A strain of music and a harmony of color afford much the same sense of pleasure to an esthetic nature. It now appears that the relation existing between a tone of color and a musical tone (that is, the fact that each color has its corresponding sound) may be put to very practical use. It is claimed to be possible, by "absorbing" a knowledge of the musical tone which belongs to each color, to cultivate an intuitive sense of music; this, however, can only be accomplished through the subconscious mind. This knowledge cannot be acquired by reason. Its possession enables the individual to assimilate music, and to memorize a composition without difficulty even without touching an instrument. Cases are cited of pianists who had been unable to memorize and who therefore could not appear in public but who, by means of color music, committed to memory and played most advanced and difficult compositions after a few hours' study of the manuscript. An interesting story is recorded of a young girl who naturally associated music and color and when asking for a particular piece would say that "pink tune," or that "red tune." It is thought that children with their receptive minds will be able easily to assimilate this new teaching, if it can be placed on a teaching basis. It might even prove a means of elevating the race by increasing the perception and love of music.

Study of the Vitality of the Blood.

Research on this subject may take at least three separate forms, viz., study of death of the red cells through the use of coloring matters, pressure, and heat respectively. For example, fresh blood is allowed to flow into a solution of methyl violet. The microscope will show that in 30 seconds the central zone of the globules is not only colored blue, but the cells are beginning to show certain morphological changes. The latter are progressive, and after four hours fragmentation occurs. Compression is effected readily in the special apparatus of Maragliano and Castellino. In this a pressure of 700 grams causes fragmentation and one of 900 grams causes complete obliteration at the end of ten seconds. When heat at 50 deg. C. is applied for 30 seconds the globules are completely destroyed. Natural necrobiosis of the red cells is unlike the preceding, for when these cells are taken from their medium, they behave physiologically for a considerable time, then perish after undergoing morphological and chromatic changes. In morbid conditions these changes may be accelerated. According to Tarchetti and Goggia (*Riforma Medica*, August 28), if red corpuscles are taken from the circulation, cautiously stained, and placed in ordinary blood plasma at from 26 to 29 degrees C., they preserve their color for 50 to 70 minutes, after which they begin to undergo complex morphological changes such as are described in all works on physiology, fragmentation appearing in 10 to 12 hours. To obtain information as to the actual vitality of blood corpuscles in a similar case a more rapid and standardized method must be used and controlled by at least two other methods, all of which have been briefly mentioned.

News of the Week.

Influenza Mortality Exceeded that of War.—A statement from the Bureau of the Census states that the influenza epidemic has thus far taken a much heavier toll of American life than has the great war. The total loss of life throughout the country is not known, but the Bureau of the Census has been publishing, for 46 large cities having a combined population estimated at 23,000,000, weekly reports showing the morality from influenza and pneumonia. These reports, which cover the period from September 8 to November 9, inclusive, show a total of 82,306 deaths from these causes. It is estimated that during a similar period of time the normal number of deaths due to influenza and pneumonia in the same cities would be about 4000, leaving approximately 78,000 as the number properly chargeable to the epidemic. The total casualties in the American Expeditionary Forces have recently been unofficially estimated at 100,000. On the basis of the number thus far reported, it may be assumed that the deaths from all causes, including disease and accidents, are probably less than 45 per cent. and may not be more than 40 per cent. of the total casualties. On this assumption, the loss of life in the American Expeditionary Forces to date is about 40,000 or 45,000. Thus, in 46 American cities having a combined population of only a little more than one-fifth the total for the country, the morality resulting from the influenza epidemic during the nine-weeks' period ended November 9 was nearly double that in the American Expeditionary Forces from the time the first contingent landed in France until the cessation of hostilities.

Influenza Reaches Alaska.—Influenza is reported to be taking a heavy toll of lives in Seward Peninsula and to be spreading still further north toward the Arctic. Of 250 Esquimaux in the vicinity of Nome only 75 are said to be left and others are dying daily. At Fort Davis seventy-five out of eighty-five soldiers have had the disease.

New York's Influenza Record.—While new cases of influenza continue to be reported in this city, the epidemic stage of the disease seems to have

passed. The records of the Health Department show that from the beginning of the epidemic until November 16, there were in the Greater City 128,558 cases of influenza and 19,091 cases of pneumonia reported, with 20,086 deaths from the two diseases.

Better Protection against Influenza for New York Children.—The New York City Health Department announces that it has instituted a service to care for well children who have been exposed to influenza or whose parents have died and left them, temporarily at least, without proper guardianship. While Health Commissioner Copeland acknowledges that this is going out of the province of the Department he believes that in the present crisis this is really the work of his department. The day nurseries of the city have been called on to assist the Department of Health in this new undertaking.

New York Infirmary Continues Campaign.—The drive to raise $200,000 for the New York Infirmary for Women and Children which has been in progress for some time will be continued until the goal set has been realized. A big benefit performance will be held at the Hudson Theatre on November 24, for which a number of theatrical stars have volunteered their services.

No Relaxation of Red Cross Work.—As a result of the armistice the American Red Cross anticipates fresh demands on its services. In order to meet these the School of Information of the New York County Chapter has decided to invite all former students to attend the sessions of the school on its reopening on November 19, when new problems arising from the changed war conditions will be taken up.

"The Buffalo Medical Journal," which was the third oldest medical journal in America, having been founded seventy-four years ago by Dr. Austin Flint, and published regularly ever since, has been purchased by and will be incorporated into the *Medical Review of Reviews.*

The National Committee for the Prevention of Blindness will hold its annual meeting at the New York Academy of Medicine, on the evening of November 26, at 8.30 o'clock. The Honorable William Fellowes Morgan will preside and Lieut.-Col. James Bordley of Baltimore, Director of the Red Cross Institute for the Blind, will speak on "Our Returned Military Blind—Plans to Prevent Lives of Helplessness."

Dr. Charles W. Page of Hartford, Conn., has been elected president of the Connecticut Children's Aid Society.

Dr. Etienne Burnet of the Pasteur Institute, Paris, and Surgeon in the French Army, and Member of the Mission of French Scholars to the United States delivered a lecture in cooperation with Columbia University at the New York Academy of Medicine, on November 15, his subject being "Pasteur as Representative of the French Scientific Spirit."

Gifts and Bequests.—Among the bequests of the late Mrs. Russell Sage to charitable institutions are the following: An endowment fund of $10,000,000 to the Russell Sage Foundation, the income to be used for the betterment of social and living conditions; to the Russell Sage Institute of Pathology, an endowment fund of $300,000; for the Association for Relief of Respectable, Aged, Indigent Females, an addition to its building on 104th Street, $25,000; Adirondack Cottage Sanitarium, $25,000; Working Girls' Home on East Twelfth Street, $25,000; to the Young Men's Christian Association, for a new building for the International Committee on Twenty-eighth Street, New York, $350,000; for addition to Y. M. C. A. building at Brooklyn Navy Yard, about $340,000; for building at Fort McKinley, Philippines, $25,000; for Long Island Railroad branch, new building at Long Island City, $100,000; for new building at Fort Slocum, $50,000.

The will of Dr. William Benjamin Hardman bequeaths $50,000 to Mercer University, Ga., of which he was chairman of the board of trustees.

Under the will of the late Gerard Beekman of Oyster Bay and New York, a bequest of $25,000 is made to the New York Hospital as a memorial to the testator's father.

Chemical Institute Planned.—At a recent meeting of the New York branch of the American Chemical Society resolutions were adopted proposing the organization of an American Chemical Institute under the auspices of the American Chemical Society. The special function of such an institute would be to promote research with a view to the introduction of new or improved medicinal products, so as to make the United States independent of any future efforts to control this field by German manufacturers. Dr. P. A. Levene of the Rockefeller Institute has pledged his earnest support to the project.

Lebanon Hospital Enlarges Facilities.—The interior of Lebanon Hospital, in the Bronx, is being rearranged and redecorated, and an addition is being built that will provide new private rooms and a maternity ward. The training school of nurses connected with the hospital is launching a new scheme whereby any young woman acceptable to the management may be prepared for the nursing profession free of charge and yet receive the monthly allowance for pupil nurses. Full particulars with reference to this plan may be obtained by writing to the Superintendent of the Training School.

Venereal Disease Committee for Syracuse.—The Mayor of Syracuse, at the suggestion of the health officer, Dr. David M. Totman, after a conference with eighteen prominent men of the city, has appointed a committee to choose a building, either in connection with one of the hospitals or a suitable location in the city, that can be converted into an isolation hospital for cases of venereal disease.

Dr. J. W. LeSeur has been appointed acting health officer of Batavia, N. Y., in the place of Dr. Victor M. Rice who has resigned to accept a captain's commission in the Medical Corps of the United States Army.

Board of Medical Examiners of Maryland.—Dr. J. McP. Scott, secretary of the Maryland Board of Medical Examiners, announces that owing to general conditions and the limited number of inquiries concerning the December examination for licenses, the Board has decided to omit this examination.

Obituary Notes.—Dr. WILLIAM BENJAMIN HARDMAN of Commerce, Ga., died of pneumonia, following influenza, at his home, on October 28, aged 53 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1890, and a trustee of Mercer University, Macon, Ga. He was a former president of the Georgia State Medical Society, and one of the party of physicians representing the American Medical Association, which made a tour of inspection of European medical universities in 1914.

Dr. JOHN E. WILSON of Denver died of pneumonia following influenza at his home, on October 25, aged 39 years. He was graduated from Harvard Medical School in 1905. He formerly practised in Colorado Springs, was surgeon for the Colorado and Southern Railroad, and lectured in the University of Colorado Medical School.

Dr. ROBERT SAMUEL TOPPING of Rutherford, N. J., a graduate of the University and Bellevue Hospital Medical College in 1911, died of influenza in the Presbyterian Hospital in Newark, on November 2.

Dr. ELIZABETH COWAN SLEIGHT died of pneumonia following influenza at her home in Mount Vernon, on November 5, aged 60 years. She was a graduate of the Woman's Medical College of New York in 1893, and was formerly connected with the New York Infirmary for Women and Children. She contracted the disease which caused her death while on duty as resident physician of the auxiliary hospital of Mount Vernon, where she was in charge of the influenza and pneumonia cases.

Dr. CALVIN FULLER KYTE, a graduate of New York University Medical College in 1881, died at his home in Jersey City, on November 8, aged 68 years. He was the oldest member in point of service on the staff of Christ Hospital, Jersey City.

Dr. THOMAS RUTHERFORD SAVAGE, a graduate of the College of Physicians and Surgeons, New York, in 1874, died at his home in New York on November 12, aged 66 years.

Dr. FREDERICK WILLIAM CUYLER LOCKWOOD, retired, a graduate of the New York University Medical College, died at his home in Cos Cob, Conn., on November 13, aged 62 years.

Dr. JOHN HENRY MACDONALD, a graduate of the New York University and Bellevue Hospital Medical College, in 1885, died of heart disease at his home in New York City on November 9.

Correspondence.

ABORTING THE GRIPPE.

To the Editor of the Medical Record:

SIR:—In your issue of the 9th inst. there appears a letter advocating with the usual therapeutic enthusiasm of its author, a justly eminent dermatologist, a method of "Aborting the Grippe," which would seem to my humble view dangerous in the extreme. Experienced physicians may not need this warning, but some young colleagues, aware of the good doctor's great reputation, may be misled. Hence this warning.

I believe that the danger from the coal-tar series is overrated. I regard them, when given in one moderate dose, invaluable in insomnia with high temperature of infectious fevers; also for certain headaches in nonfebrile conditions. But I must protest against giving 7½ grains of phenacetin every two hours for two days to a child thirteen years old.

I know of two cases of nephritis in elderly men traceable to the habitual use of these drugs. One has been cured and the other continues because that habit continues. The first case is of a man who has during the past few years become a great figure in history, who has been saved to the world by his skillful physician. The latter discovered that the patient had albumin and casts in the urine, and was often cyanotic. Inquiring closely into his habits, the doctor discovered that the patient was taking powders containing phenacetin, acetanilid and salicin, for colds. He abandoned this medication and placed the patient under hygienic conditions, golfing, etc., which converted him into one of the most robust men of his age that I have ever seen. The patient had used these powders for years, and regarded them as indispensable.

SIMON BARUCH, M.D.
51 WEST SEVENTIETH STREET, NEW YORK.

THE ALKALINE TREATMENT OF INFLUENZA.

To the Editor of the Medical Record:

SIR:—In your issue of Novebmer 9, 1918, there is an article by Dr. L. Duncan Bulkley on the value of sodium carbonate with phenacetin in aborting the grippe, to which I wish to add my mite. Away back in 1876 I was a pupil of Dr. Bulkley's at the old Demilt Dispensary, and there I learned to value his opinion. He has had a vast experience, and any statement he makes should have respectful hearing. That it is right to create an alkaline condition in a person exposed to a cold of any form or the grippe, I firmly believe, and to my own satisfaction I have verified the efficacy of the alkaline treatment in a general country practice of more than forty years.

It is not necessary here to attempt to account for the good results of the sodium bicarbonate treatment. Whether it combats the acidosis or inhibits the growth of the bacteria causing the disease, or both, may be left for another time. In 1875 my father, who was a practitioner of medicine, taught me the value of sodium bicarbonate in colds, especially when the larynx was involved, producing the customary croupy cough of children. Later, in pneumonia, patients seemed to do better when on alkaline treatment than any other; and finally it became my custom to give alkaline treatment where catarrhal and edematous conditions existed.

In this present epidemic the mortality from lung complications has been unusually large in Circleville, which is only sixteen miles from Camp Sherman, but I have had the same gratifying success with the sodium bicarbonate treatment as formerly. The edema which makes the lung complication so fatal seems to be absent when the patient is treated with alkalines. It is, however, not an eleventh-hour treatment. In the very beginning of the grippe I give 30 gr. of sodium bicarbonate every two hours. If there is much aching, instead of Dr. Bulkley's

10. gr. of phenacetin I have been giving 5 gr. each of phenacetin and strontium salicylate every four or five hours as long as the aching continues. This seems to act promptly in connection with the sodium bicarbonate. When there is no secondary infection the speed with which patients with grippe recover under the sodium bicarbonate treatment is very gratifying. Out of several hundred cases in the present epidemic I have had but seventeen of bronchopneumonia as a complication, and these have all recovered. In all cases I have insisted upon plenty of fresh air, plenty of water, no food unless relished, and good general nursing. I have given some morphine and some codeine when pain or cough demanded it.

I am not much of a believer in empirical medication, but I began the sodium bicarbonate treatment of colds and pneumonia in the days of empiricism, and I am pleased to believe that the laboratory has confirmed the value of alkaline treatment in the types of diseases in which I formerly prescribed it empirically.

HOWARD JONES, M.D.

CIRCLEVILLE, OHIO.

THE DRUG COMMISSIONER.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—It is reported from Albany, in a despatch to a New York newspaper, that Senator Whitney, the chairman of the Drug Investigation Committee, which after two years of labor brought in the bill for a Drug Commission for the State, cannot be appointed to the office of drug commissioner, a $6,000 a year berth extending over a period of six years. This appointment, it is said, may be left to the incoming Governor, as a senator cannot be appointed to a State office during his term as Senator, which expires in this instance on December 31, 1918. It appears, according to the published account of this matter, that Senator Whitney declined a nomination for Senator, an office he has held for many years, in the expectation of this new honor from the State. The fact that the "Great Drug Problem" has resolved itself into a commission form of control as a solution for its evils, like other State problems, such as pugilism and racing, is a matter to be deplored.

The Drug Commission will have many great and unusual powers and privileges over the practice of medicine, as well as over those "addicted" to the use of drugs. In Massachusetts, drug addiction has been judicially declared a "vice," and physicians have been sentenced to jail for not prescribing for addicts in accordance with the medical views of the court.

This extreme view does not obtain here, as yet, and it is of great importance to the medical profession that the Drug Commission should have more of a general knowledge of drugs and medical practice than can be obtained by the practice of law or while a justice in the criminal courts. In this respect Senator Whitney as a druggist and as an experienced legislator has much to recommend his candidacy over that of the ordinary politico-legal appointee. So far as is known up to the present time, the great medical bodies, such as the State and County Medical Societies, are never consulted in appointments so closely related to their affairs as that of Drug Commissioner. Perhaps under this law, as in the original law for a commissioner of health of this city, a physician is ineligible for drug commissioner. Whether he is or not, it is not likely that his views or those of the representative medical bodies of the State will be taken into consideration in filling this office, all of which may be said to be due to the indifference of medical men to matters of medical legislation.

JOHN P. DAVIN, M.D.

NEW YORK.

DR. L. H. BUNNELL, MEDICAL EXPLORER.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The excellent article by Dr. William Browning in the MEDICAL RECORD of October 26, 1918, would (to your readers of the Pacific Coast) seem more complete if the work of Dr. L. H. Bunnell had been noted. He was a surgeon of the Maraposa Battalion, under the command of Major Savage, a veteran Indian fighter, and with the Savage party descended into the Yosemite Valley in a campaign against Tenaya and his band of renegade marauders, March 21, 1851.

He wrote a book on this discovery that is a frontier classic. To him and his courageous companions forever will remain the honor of first visiting this mysterious valley and making known to the world the majesty and splendor of its unsurpassed scenic beauty. The Indian name for this valley was Ah-wah-nee, meaning "grassy vale." Dr. Bunnell proposed to name it for the tribe of Indians inhabiting it, "Yosemite" (meaning Grizzly Bear). This name was accepted by his brave companions in arms.

It would be scant justice to the memory and merit of the intrepid Dr. L. H. Bunnell if his name is not included in the list of Dr. Browning's immortals.

H. E. W. BARNES, M.D.

SANTA ANA, CALIFORNIA.

SCRAP PLATINUM NO LONGER NEEDED.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The Platinum Section and the Section of Medical Industry, War Industries Board, desire to express appreciation of the hearty response made by physicians, dentists, and others when the call for scrap platinum was made. As the governmental demand for platinum in the making of explosives, etc., has been tremendously decreased by the curtailed war program, it is requested that no further scrap platinum be tendered to the Government through the channels indicated in our communication of September 17, 1918.

CHARLES H. CONNER,
Chief Platinum Section.

LIEUT.-COL. F. F. SIMPSON, M. C., U. S. A.,
Chief of Section of Medical Industry.

Pithiatic Perturbations.—Vampré reports a case of hysterical manifestations of 17 years' standing. At present the patient has a contracture of the fingers of the left hand involving complete immobilization for 4 months.—*Annales Paulistas de Medicina e Cirurgia.*

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE INFLUENZA EPIDEMIC—THE ABOLITION OF JURIES AND MEDICAL JURISPRUDENCE—WOMEN IN PARLIAMENT—THE EGG SHORTAGE.

London, October 24, 1918.

THERE is a story of an Eastern pilgrim who, on his peregrination, met the Plague, and asked it its destination. "Bagdad," replied the Plague, "to kill 5000 persons." Later the pilgrim met the Plague again, and asked it why it had changed its mind, and killed 50,000 persons, to which the Plague replied: "I did not change my mind. I killed 5,000 persons; the other 45,000 died of terror." The story has a moral for this country at the present moment, when we are suffering from a severe visitation of influenza, if we substitute for the word "killed" the word "attacked." A vast number of the so-called cases of influenza have undoubtedly been severe cases of catarrh, running a protracted course owing to the mental depression of the attacked. And the necessary inconveniences of illness attacking large communities have been and are being aggravated by war conditions; shortage of doctors, rationing of supplies, restriction of traffic, by train and road, congestion of telegraph and telephone stations—these are a few of the obvious factors which tend by their aggregate influences to depress the population. And undoubtedly the number of cases of true influenza—whatever that may be—has been very large; in certain localities an epidemic of a severe and even dangerous type has occurred.

Rather late in the day the local Government Board has issued a public notice of instructions with regard to prophylaxis; the instructions are of the most obvious sort, but their value is much impaired by their non-appearance until the disease was in full swing in many districts. The advice of the local Government Board is of the usual pattern, and includes recommendations to avoid worry, overwork and unnecessary exposure, to keep warm and take proper nourishment. Fortunately, although we are in the fifth year of war, and although the many inconveniences I have already detailed, do not tend to diminish, still there is nothing approaching disorganization in any of our public or medical services. The instructions of the Local Government Board can be followed, as we have the reserves even under the added strain, but these instructions would have been worth incalculably more in the first or second week of September, when only sporadic visitation had occurred. It is by the way fortunate that no great military centers, camps or munition works have been attacked in undue proportion. For at a critical stage in the war that might have constituted a grave international affair.

Progressive medicine of course is looking in one main direction for the efficient prophylaxis—namely the preparation of an effective vaccine, but the bacteriology of what may be roughly termed "influenza catarrhs" is yet very undecided. Undoubtedly Pfeiffer's bacillus is the peccant body in a majority of cases, but this bacillus can be present in catarrhs presenting no similarity to typical influenza, and, moreover, can be absent in conditions of classic influenza. In the epidemic now visiting England and Scotland it is largely absent, and a streptococcus frequently present. A conference has been sitting in London under the chairmanship of Sir William Leishman, to inquire into the bacteriology of influenza and its congeners and the result will be the preparation in various ways of various polyvalent vaccines which will then be made the subject of trial on large scales. In this way there ought to be progress made to some prophylactic measure a little ahead of the grandmother's advice to keep warm and not to worry. It is unlucky that the last great and dangerous epidemic of influenza in England occurred 30 years ago, when the doctrines of vaccinal protection were hardly enunciated.

It is not so much a shortage of material from which to select "twelve good and true citizens," as a growing disbelief in the discretion of the twelve when selected, that has led to the considerable abolition of juries in this country. An act has been passed enabling judges of the High Courts to sit without juries in all civil cases except a small group, of which libel cases are the most important. Similarly coroners have been granted discretion as to holding inquests without juries in all cases where no question of crime is raised. The effect of this partial disappearance of juries upon medical evidence may be very valuable. Judges and coroners have not always shown themselves particularly intellectual recipients of medical evidence, but the scientific or professional side of medical matters can be expressed to an educated man in a way which it cannot be made clear to persons of the mental equipment or the ordinary jury. The difficulty in which a doctor is placed to make clear a pathological problem to a jury is very great, and when a cross-examining counsel attempts to obscure the issues the difficulty becomes insurmountable. He hesitates, he appears to contradict himself, he appears also to contradict other medical evidence, and he produces the impression of being an untrustworthy witness when he is trying to be a conscientious one. It is true that the judge may and should appreciate the position and it is true that he may and probably will try to make matters clear to the jury in his charges to them; but it is the jury that gives the verdict, and juries dislike dictation. If the jury thinks the medical evidence unreliable, because it is incomprehensible to them, they will give their verdict in accordance with their view whatever any judge may say. Medical witnesses will have no regret for the passing of the jury.

Against a negligible minority the House of Commons has decided that women, who have now obtained the parliamentary vote, have the right to represent that vote in actual legislation. Medicine comes in here in rather an amusing way, and yet a way that has its serious side. When the female suffrage movement began to assume appreciable proportion medicine presented toward it a double front. On the one hand the protagonists of the movement numbered many medical women, and the successful conduct by women of a very important side of professional life was one of the best arguments put forward by the female

suffrage party. On the other hand it was to physiology that the opponents to women's suffrage looked for their scientific effort, inasmuch as the pleas of equality of the sexes could be upset on the obvious ground that physiologically the sexes were not alike, did not play the same parts in any biological schemes, and were different in the risks to which they were exposed and the strains which they were able to bear. Medical men asked if it would not be rather awkward if the female minister of war found herself in child-bed on the eve of a war, to which the female suffragists replied that they were asking for a parliamentary vote, not for a seat in Parliament, and that the jibe was a deliberately unfair one. The reply was politic, but not frank. The demand for a vote was backed by women who actually disclaimed any idea of seats in Parliament for women, and in this way a great majority of women demanded the vote. But the more hard-headed leaders of the movement knew perfectly well that when the vote was granted the seat would follow—in other words they knew perfectly well that the instance of a pregnant politician was no jibe but a prophecy.

The egg shortage has become severe, and I do not suppose the censor will mind its being mentioned, though, judging by recent documents, the fact may bring some pleasure to Germany. For it is our wounded that suffer. The demands of the hospitals for a constant supply of fresh eggs is enormous, and the country is determined to meet it, though the Food Control Department does its best in the reverse direction. The present government ration is barely sufficient for breeding purposes and if it is not supplemented eggs will temporarily disappear from diet sheets. Doctors know that this would mean in the treatment and after treatment of some of the severest conditions with which they meet.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

THE SPANISH GRIPPE AGAIN BEFORE THE ACADEMY—THE PARIS COMMITTEE FOR WAR NERVE DISEASES.

PARIS, October 14, 1918.

M. ROUX, director of the Pasteur Institute, presented two reports to the Academy of Medicine upon the different manifestations of the present epidemic of grippe, one by Drs. Anthony and Orticoni and one by Drs. March-Hadour and Denier. The first mentioned in all of their cases remarked from the onset grave signs of infection. The cases were complicated by pneumonia and purulent pleurisy. A special condition noted was that the bacilli of Pfeiffer were found in both the blood and the liquid of the pleural cavity and were absent in the expectoration, only the pneumococci being present. The cases observed by Drs. March-Hadour and Denier were equally grave. It made its appearance in the midst of the fleet at Brest, attacking by preference the young recruits and caused the death of 53. The symptoms of invasion were always severe, chill, fever, cyanosis of face and hands with early advent of a cough and thick purulent expectoration similar to pneumonia. The tongue heavily coated and every evidence of profound infection. The heart's action usually rapid accompanied by profound adynamia. Pericarditis was a frequent complication. Recovering from the attack the patient remained for a long time feeble and anemic. Blood cultures exhibited streptococci of exceptional virulence. A local doctor accidentally inoculated by these streptococci died in a few days showing grave symptoms against which all remedies proved powerless. In both of these reports it is stated that the microbe is found in the blood, which doubtless accounts for the exceptional gravity and multiple complications observed.

Since the outbreak of the war there has been such an extension of nerve trouble among wounded men that a committee was founded in Paris to do the utmost possible to relieve the sufferings of those victims of the Huns' frightfulness. The committee includes several members of the Academie Française, notably M. Emile Boutroux, M. Maurice Donnay, M. Anatole France, M. Henri de Regnier and M. Ernest Lavisse, and a number of ladies. Invaluable work has been done by this organization which is operating with the authorization of the French Government under the title "L'Assistance aux Blessés Nerveux de la Guerre." So much expenditure is involved that the committee now requires new funds. In a pathetic appeal for new subscriptions the society mentions that, besides the unhappy invalids deeply struck with nervous disease, incurable and socially speaking useless, there are numerous wounded men, physically or morally lessened in strength, but capable of improvement, when placed in special conditions, and who may become, to a certain degree, fit to take up again their work. If these are reeducated but left to themselves, they do not readily find employment; when they find it, some of them are not able to keep it more than a short time, either because their weakened health causes in them a lack of energy and perseverance, or because they may appear more awkward than useful to their employers. The society's aim is to find these men appropriate employment in order to lighten in every possible way the burden of their infirmity through social life.

3. Acute Eczema Due to Faulty Metabolism of Food Elements.—Louis Fischer submits a discussion, based on his own clinical experience, of the view that internal, physical, and toxic conditions may be the cause of acute eczema. From a study of a large series of cases he has found that intestinal derangements due to faulty diet or excessive feeding cause eczema, and cites three cases of persistent infantile eczema in which marked improvement rapidly followed the elimination from the

diet of excessive fat and carbohydrates, which had induced faulty metabolism and resulted in the eczema. Fischer found that in both acute and subacute eczemas the internal administration of the lactic acid bacillus, or the Bulgarian bacillus in pure culture, could be given after each milk feeding. When, however, Bulgarian milk or buttermilk was given, the improvement noted was more rapid and steady. Meat, the protein of fish, and white of egg were found to have a peculiar tendency to irritate. Milk is a special article of diet, but was not as beneficial as sour milk. By using the Bulgarian bacillus the casein is transformed into casein lactate, to which the excellent effects are due. Vegetables in the form of spinach, peas, string beans, sprouts, and even cabbage are well borne and have a laxative effect; they aid in removing putrefactive bacteria, and their earthy salts have a decided nutritive value; moreover, they do not heat the body as do the carbohydrates. Water should be given frequently, in order that toxic products may be eliminated through the kidneys. Itching and excoriation may be greatly modified by feeding large quantities of bicarbonate of soda in water—one-half teaspoonful of bicarbonate of soda may be given every hour by mouth. The infant, of course, must not be disturbed during sleep. Active catharsis, by giving fifteen to thirty grains of phosphate of soda in water several times a day, is of marked benefit. To effect a cure, Fischer insists upon the diet being continued for at least from six months to one year.

1. Military Aspect of Status Lymphaticus.—James Ewing discusses constitutional predisposition to disease as evidenced in military life by "irritable heart," "irritable thyroid," nervous instability, or functional shell shock, all of which are due chiefly to anatomical defects. Since such defects cannot be remedied, the question arises whether they can be recognized and prevented. In status lymphaticus it is possible to recognize pronounced forms during life and to a considerable extent to avoid its dangers. This condition is characterized by a feminine type of conformation in the male, absence of auxiliary and deficiency of pubic hair, delicacy of integument, tendency to deposits of subcutaneous fat, rickets, small size of heart and thinness of aorta and other arteries, persistence of thymus, and hyperplasia of lymphatic tissues in tonsillar ring, ileum, and spleen. In infants and before puberty, lymphatic hyperplasia, large thymus, and signs of rickets are prominent, while in adults the lymphatic hyperplasia is succeeded by atrophy and by a form of sclerosis. In the female, thinness and delicacy of skin, narrow waist, arched thighs, and scanty hair are among the external signs; there is usually delayed menstruation, the uterus may be infantile, and the breasts poorly developed. Thymic pressure is probably one of the chief factors of death in infants. In about 80 per cent. of cases the pharyngeal ring of lymph follicles is enlarged, the lingual follicles being affected more than the faucial tonsils. The splenic follicles are enlarged and structural changes consist of overgrowth of lymph follicles and lymphocytes. Degenerative and necrotic changes occur in the centers of follicles and are followed by sclerosis (Symmers). At necropsy, hypoplasia of heart and aorta are found. (In four of Woodward's cases the heart weighed 5½ ounces or less, and in one only 4 ounces.) The condition is one in which the endocrine glands and the nervous system are involved, and is relatively common in the mental deficient. It is pronounced in cases of suicide. The entire cerebral vascular system is probably involved, a fact which may prove of importance in aviation. Cameron attributes lymphatic hyperplasia to chronic inflammation of the mucous membranes, due to poor hygiene and excessive carbohydrate feeding, whereas Blumer and Symmers favor the idea of autointoxication. Ewing considers the condition principally from the military standpoint. He points out that in the lesser grades of status lymphaticus the signs are not definite enough to be of diagnostic value. In obvious cases, however, or cases of irritable heart, thyroidism, nervous breakdown, epilepsy, shell shock and fulminant infectious diseases, status lymphaticus should be looked for. It is evident from the fact that the disease is one which carries with it a defective vitality which results in sudden death in many conditions of trauma and disease that every effort should be made to detect its presence, and nowhere can this be done so well as in the army. If not rejected as unfit for military service, subjects should at least be given the less hazardous and taxing duties. Evidences of the condition should be looked for at every postmortem and the anatomic changes noted for future reference. Histologic studies are also required on the thymus, thyroid, hypophysis, pineal gland, carotid gland, pancreas, suprarenal, testis, sympathetic system, bones and bone marrow, and particular attention should be paid to the circulatory system. Of course, the final test of the existence of such a condition must be clinical and particularly in the lesser forms of the disease are keen observation and sound clinical judgment essential. The existence of status lymphaticus is of the greatest importance in the choice and administration of anesthetics, as the possibility of death from respiratory failure must be remembered. Great care must also be exercised in the injection of alien proteins and arsphenamine. According to Bartels, subjects of status lymphaticus acquire a resistance to tuberculosis, and it is almost exclusively in such subjects that Addison's disease occurs. Moreover, these subjects do badly under infection and it is possible that a fulminant course of meningitis or pneumonia is largely determined by status lymphaticus. The author remarks that it would be of interest to determine what proportion of patients with shell shock and other forms of nervous breakdown are subjects of status lymphaticus. He adds, however, that such study must be undertaken with the greatest caution or the condition will be lost in a maze of minor clinical disorders.

3. A Case of Absence of All Sensation.—Captain E. D. Roberts reports a case of a Breton sailor, aged

thirty-seven, who emigrated to Canada eight years ago and enlisted in the Canadian Army in 1916. In June, 1918, he was admitted to hospital at Aldershot for mumps. This man exhibited complete absence of both superficial and deep tactile sense over the whole skin surface and also over mucous membranes where attainable. Sense of pain was completely absent (In 1916 patient underwent the radical cure of double inguinal hernia without anesthetic and without feeling any pain), and even the cornea shared in the general anesthesia. Thermal sensation was also absent; upon placing the hand in water hot enough to raise a blister there was a slight convulsive movement and patient was conscious of what he described as an "electric shock," but the feeling was not painful. Cold water evoked no sensation; neither did atmospheric changes affect the patient. Muscular sense appeared to be completely absent in this man. With eyes closed he could not distinguish between a heavy weight placed in one hand and a light object in the other. He was, however, able to walk with eyes closed and was a good swimmer. He felt no fatigue and stated that the only way he became aware of failing strength under prolonged effort was by falling to the ground. Sense of position was also absent and was accompanied by fixation of limbs, that is, if the man's eyes were closed and his limbs placed in a certain position by the observer, he was totally unaware of being touched. In addition there was complete absence of sense of taste; the patient ate anything and on one occasion consumed a lump of bath brick; he stated that he was in the habit of eating rats, mice, dog or serpent uncooked. He stated that he was never conscious of hunger or thirst and, for a bet, once went without food or drink for eight days without inconvenience or ill effects beyond an abnormal tendency to sleep. Sense of smell was practically nonexistent. Patellar reflexes were normal, the orbicularis palpebrarum muscles contracted in touching the cornea but evoked no sensation; pupils reacted. There was never desire to defecate or micturate, but both took place once in the twenty-four hours at about 8 a.m., and patient said that as a precaution he gave himself the opportunity to pass urine also at about 4 p.m., but often without result. Patient moreover seemed to lack most of the common emotions and to be without family affection or love of country; he made neither friends nor enemies. However, he was always ready and willing to help in hospital duties. The history of this case showed that as a child the patient possessed a slight degree of cutaneous sensibility, its complete absence dating from an attack of yellow fever in Senegal when he was seventeen years of age; otherwise he had enjoyed robust health. A provisional diagnosis of syringomyelia combined with hysteria was made.

4. The Prevention of Relapse in Hysterical Manifestations.—Captain T. A. Ross points out the distinction between the removal of hysterical symptoms and the "cure" of the patient. The removal of symptoms is not sufficient, for that which underlay the hysterical manifestation remains untouched, and therefore one of two things will happen, the patient will either begin to complain of other symptoms, such as headache, or during emotional stress the symptoms will reappear. In order to prevent recurrence, every patient should be instructed that his symptoms may return as an emotional reaction, but that such reaction will not persist and little inconvenience will be caused. It is essential that the patient should be cured without the employment of any agent or apparatus; otherwise he will feel that he cannot effect a cure himself without the aid of this same agent. Relapse may also be prevented—and perhaps in a better way—by careful inquiry to ascertain why the patient ever had hysterical symptoms, for instance, fear of insanity, fear that he had been a coward, and so on. Patience will be required in many cases, but this underlying cause can be elicited. By persuasion and suggestion in the course of conversation the cause of the hysteria may be dissipated, but it is important that the reason for the symptoms should be made perfectly clear to the patient, or he will certainly relapse. It will be found that when the patient's mind has been relieved by getting him to see his trouble in a different light, his capacity to withstand emotional reactions will be greatly increased.

Berliner klinische Wochenschrift.

September 9, 1918.

Experiments in the Use of Quinidine in "Absolute" Arrhythmia.—W. Frey refers to his former articles on this subject (*Berliner klin. Woch.*, 1918, Nos. 18 and 19). His electrocardiographic studies bring him to the following conclusions: (1) Quinidine combined or not with digitalis causes the disappearance of the fibrillation of the auricles in about 50 per cent of cases, as well as the very irregular arrhythmia which is a dependant upon it. This medicament must be prudently dosed as certain subjects possess an idiosyncrasy in respect to it. (2) Quinidine exercises a depressive action over the contractile property of the myocardium. The pulse is not affected in its energy, the ventricular systole being slightly prolonged. On the electrocardiogram the T-wave is lowered, a fact which the writer connects with a vagotropic action, inhibitory of the metabolism of the cardiac tissue. The precision of the fibrillation may be summed up, in other words, in an inhibition of excitation and excitability in the auricle. The regular rhythm when once re-established is accompanied by an extension of the arterioventricular conduction.

The Nature and Effects of Food During War.—A. Loewy and C. Brahm read a paper on this subject in which the following official statistics are of some interest:

	April, 1916	June, 1916	April, 1917
Albumin consumed daily by an adult	68.29	66.77	55.93
Calories per day and per person..	2320	2230	1985

Other statistics give:

Producers (peasants, etc.), albumin per day, 100.7, calories 3194.

Non-producers (well-to-do), albumin per day, 75.65, calories 2284.

Non-producers (small means), albumin per day, 54.4, calories, 2243.

In producers the loss in weight in 1917 was 0.9 per cent, while in non-producers it was 12.2 per cent for males and 6.8 per cent for females. The writers have studied the effect of an alimentation of more than 1000 calories and one of less than 2000 calories. The subjects submitted to the latter regimen had a negative nitrogen elimination (that is to say, they did not assimilate the albumins). In the other class the nitrogen output was stationary even in the case of obese subjects before the war and having attained the weight of 50 kilos. Therefore, the writers found that in the latter class a new equilibrium in the organic changes became established and remained fixed with a daily ration of 2000 calories.

Münchener medizinische Wochenschrift.

September 3, 1918.

Treatment of Gout and Other Chronic Articular Inflammatory Processes with Extracts of Cartilage.—E.

Heiler builds this treatment upon a series of reasonings as follows: All organic tissues are called upon to live in permanent contact with various products of waste or of disintegration of normal metabolism. In order to defend themselves against the toxic action of these products, the tissues elaborate physiologically certain defensive substances which prevent the action of these products of metabolism upon the tissues. The writer recalls the similarity of this conception with the well established fact of the immunity of the gastric mucosa in relation to the gastric juices. He calls this fundamental property of the tissues a "local tissue defense." A disturbance of this function may involve one or several of the products of metabolism. Therefore, gout represents an attack upon the tissues deprived of their ordinary means of defense against uric acid by this puric derivative. The elective localization of the affection to the articular cartilages is due to the predilection of this tissue for uric acid. In the absence of, or the insufficiency of tissue defense against uric acid, the chondral tissue is the first to become impregnated with uric acid and thus offers the well-known clinical picture of gout. Therefore, the writer endeavors to stimulate the defense of the cartilage against uric acid by injecting extracts of cartilage. He thinks that by this means he has obtained encouraging results not only in gout, but also in cases of arthritis deformans. Extracts of calves' cartilage, or better still that of the fetus of a calf, possess a more marked action than the cartilage of adult animals. The writer explains this fact by the greater intensive metabolism of young animals necessitating a greater tissue defense.

Deutsche medizinische Wochenschrift.

September 5, 1918.

Treatment of Malaria by the Quinine Alkaloids and Their Chemical Substitutes.—J. Morgenroth justifies in the continuation of his paper the important assertion he made, namely, that quinine given per os or subcutaneously tends to accumulate in the red blood corpuscles. This remark is true for both quinine and its various alkaloids. Morgenroth's demonstration is made by three series of experiments: (1) The anesthetic action on the heart of rabbits. This is more marked in the case of a suspension of corpuscles first treated with quinine than for a watery solution of the same concentration or the primary blood mixture. (2) The greater antiseptic action of sera mixed with quinine than that of the total blood mass treated in the same way. (3) The proof derived from the hemolytic action of globular suspensions treated with quinine. This fundamental fact having been established, Morgenroth passes to the study of the probable mechanisms of the antiparasitic action of the quinine alkaloids. This action may be: (a) Ectoglobular, a possibility already discussed and refuted by the writer. (b) Endoglobular. This is rendered probable by the storing up of the alkaloids in the red blood corpuscles. (c) An action of repulsion. The mesozoite coming in contact with a red blood corpuscle charged with quinine is unable to penetrate it, and therefore is condemned to perish in the blood serum. The writer appears to attach considerable importance to this means of defense of the organism against the parasite so that treatment should have as an object saturation of the blood with quinine at the time that the schizontes burst forth as well as the dissemination of the merozoites. Finally, Morgenroth puts forward the problem of the comparative action of quinine and its various alkaloids. For example, optoclime possesses a more effective action in the trypomosomiases and malaria and the same applies to hydroquinine.

The Biology of Koch's Bacilli.—G. Lockemann concludes a series of studies on the influence of the conditions of development; the vitality, morphology, chemism, etc, of the bacillus of tuberculosis. The writer has gone to much pains to demonstrate what has been known in all countries outside of Germany for a long time.

La Presse Médicale.

October 10, 1918.

Pandemic of Influenza.—Violle first lays the rumor that the present affection has anything actually in common with the pneumonic pestilence of Manchuria, although there is an accidental resemblance thereto. The former is spread purely as pneumonia and is not grafted on influenza. The causation of the deadly Manchurian plague is, of course, quite absent in the present pandemic. The idea of wearing the gauze mask may have been suggested by the same custom, which is absolutely essential to the protection of the doctor and nurse in the Asiatic pestilence, but as yet we do not know that it is a complete safeguard in influenza. Attempts to connect it with other epidemic maladies are no better justified. The disease is simply influenza as we have known it for centuries—grippe in pandemic incidence. The present wave started from the Oriental Mediterranean several months before it was recognized and where it would be readily masked by certain endemic maladies as three-day fever. The earliest cases were both mild and scattered. Even the outbreak in Spain was almost benign. Just why it should first become pandemic in that country is not apparent, for Spain was not engaged in warfare, and the war is certainly responsible for the behavior of the epidemic. The latter appeared to gain virulence as it traveled north. The cold of the more northerly countries seemed to act as a check, which of course has not been apparent until recently. At least it was noted that the spread was again changed toward the South. In this capacity it did little execution, evidently because some immunity had been gained by the victims. In this connection it has been noted that mild cases as well as severe ones must be reckoned in the total—even cases so mild that they pass for a slight coryza—nay, even unmotivated lassitude without coryzal symptoms must be regarded as a possible grippe equivalent. But it is only too evident that we cannot speak of acquired immunity of the type seen in measles, for example. Incubation is of the briefest, not over twenty-four hours. Prodromes are absent and the onset is especially violent. Fortunately, and not realized sufficiently, the normal course is brief—one day, two days, rather than longer. Three or four days are really seen in the minority of patients. But weeks pass before the subject recovers fully. Death from influenza *per se* seems due to the action of the toxins on the medulla, one expression being acute edema of the lungs. When we consider the global incidence the case mortality must be ranked as low. We no longer look upon the familiar bacteria of sporadic grippe as the cause of the pandemic. Much more probably is it a filtrable virus which eludes us just as the cause of measles and scarlet fever eludes us. Filtered blood serum is as toxic and infectious as unfiltered. Outside of the body fluids the cause has little viability. The unknown cause can certainly devitalize the body and make it an easy prey for epiphytes roused to virulence. This greatly lowered resistance stands in some intimate relation to the *asthenia paradoxa* of the disease. Nicolle writes instructively of what he terms the *microbes de sortie*, which play a rôle in all epidemics. Thus in hog cholera the primum mobile is an invisible and filtrable organism which attacks the animals and alone would not give rise to the disease. Invariably, however, an epiphyte bacillus of the paratyphus type makes a sortie and the result is a symbiosis which causes hog cholera. Pathologists are seriously entertaining the theory that even the bacillus typhosus and cholera vibrio are microbes *de sortie*. We are now able to state that Pfeiffer's influenza germ is only a microbe of this type, for the present pandemic has proved it. It must henceforth take its place with the pneumococcus, streptococcus and other domestic germ life. These superinfection germs destroy life. The grippe sentences the victim, but the complication executes the sentence. In this connection the keystone of the treatment should be, in the pneumococcus case at least, the proper antiserum used as prophylactic. Injections should be made as soon as the influenza is in the least suggested. Nothing is said of immunizing the healthy in this connection. There is but one risk run, to wit, that the pneumococcus may not be the active agent. This can only be determined by rapid examination of smears. In pneumococcus cases the results are surprisingly good. Even after double pneumonia has developed the injections should be tested, for some desperate cases have been saved. The author has had little experience with streptococcus and polyvalent sera, as in his vicinity the pneumo-

coccus was the dominant germ—only the outnumbering microbe is considered in serotherapy. The author has vaccinated the healthy exposed subject, but as all other precautions are taken the exact result cannot yet be determined. Convalescent blood, while impracticable, is clearly specific both as a cure and preventive.

On Phenolphthalein as a Test for Renal Function.—Motzfeldt first gives a short review of the relative value of the different tests for estimating the functional activity of the kidneys, and enumerates the more important articles on phthalein. His own conclusions are drawn from observation of a clinical material of 136 patients, of which number 61 suffered from nephritis. The method used was the well known one of Rowntree and Geraghty—intramuscular injections in the lumbar region and estimation of output for two hours. The excretion of healthy kidneys is shown in a separate table. In the author's Table III it is shown that in cases where the excretion is distinctly delayed the differences after intravenous and intramuscular injections are very slight. The author is able to show also that the excretion depends on the amount of urine secreted in the two hour period. He contrasts the phthalein elimination with the presence of edema, hypertrophy of heart, systolic blood pressure and urea content of the blood, and reaches the following conclusions: The test is very valuable, and if one can make but one test, is dependable. Its simplicity makes it readily carried out by any practitioner. In subjects with normal kidneys the author has never seen excretion delayed, save slightly in cardiac patients. The average excretion for normal organs is 65 per cent of the whole and the lowest limit 50 per cent. Since in many cases of nephritis excretion is normal, the test can give no direct information as to presence or absence of this condition. It does, on the other hand, show presence or absence of functional impairment or insufficiency, and delayed excretion is always a grave sign in both acute and chronic conditions. Whenever there is delayed excretion the blood should be examined for its nitrogen content. Whenever excretion reaches 25 per cent nitrogen retention may be anticipated. The test is of much diagnostic and prognostic value when uremia is actually present. There is no relationship between phthalein excretion and albuminuria, edema, or hypertrophy of the heart.

Typhus Fever.—Hitzig, of Mexico City, contributes this article. The literature of the subject has now become enormous, because of late years the disease has regained some of its lost prestige as a European pestilence. The first certain description of typhus goes back to 1521. Its tendency has always been to lurk where the people are unusually poor and insanitary—Ireland, Poland, Galicia, the high lands of Mexico, etc. From such foci it was generalized by wars. Very striking was its failure to appear in the Franco-Prussian War and on the West Front in the present conflict. It has not always been spread by war, however. for in 1848 it invaded England from Ireland and there were more than a million cases as a result. That it has never attacked the Mexican coast is due clearly to the greater cleanliness of the people, who can bathe in the sea the year around and also keep their clothing clean and hence changed. It changed from endemic to epidemic largely because of the civil wars. Virulence varies directly with underfeeding—the prosperous have a mortality of but 10 per cent., while among the indigent it is four to five fold that figure. Of possible bacteriological causes the author discusses the Ploetz bacillus, the Weil-Felix proteus, and the Rickettsia. Ploetz and coadjutators would render a great service by going over the work of their competitors—especially Ploetz seems never to have worked with lice. It is not unlikely that the germ may be diffused by droplet infection—when there are complications in the bronchial passages—and by the dust storms that occur in Mexico. That the louse body may be made to transmit the disease, that the microorganism is able to provoke an endarteritis obliterans in connection with the roseola, that petechiæ may be artificially provoked, are well verified results of experiment. In Mexico beginning typhus simulates grip, while in the child measles has to be excluded. As variola occurs in this country it also must be excluded at the earliest possible moment. Yellow fever occurs exactly where typhus does not—on the litoral, never on the table lands. If the exanthem fails the author has much faith in the efficacy of the Weil-Felix reaction. This, however, is not obtainable until about the seventh day. Preventive measures of a biological type have not been tried in Mexico, nor, apparently, therapeutic measures of the same type. The author only mentions quinine in his personal experience and apparently more as a preventive than curative remedy. Treatment is wholly symptomatic. Here belong saline in fusion, digitalis, camphor, lumbar puncture, etc.

Pneumococcemias in Children.—D'Espine and Reh of the pediatric clinic in Geneva have long practised hemocultures in febrile affections and have thereby secured a large body of information about the activities of the pneumococcus. Four categories of localization readily group themselves, viz.: pleuropulmonary, meningeal, anginal and pure sepsis. The total death rate from pneumonia is very low, for in eight years there were but sixteen deaths among 406 pneumonia patients. Among these few deaths were two of unexplained virulence in children of one family in whom precocious empyema developed. Such cases have been extremely infrequent. On the other hand, pneumococcus meningitis proved very deadly with eight deaths out of nine cases. Suppuration, so rare in pleuropneumonia, seems to be the rule here. In one case there was a mixed infection of pneumococci and meningococci, a combination usually fatal, yet this patient recovered under serum treatment. Under angina the authors mention only one case in which there was positive hemoculture, as an example of benign pneumococcemia. In regard to pure sepsis of severe degree, i.e. pneumococcemia with clinical sepsis, one case is mentioned in which recovery followed intravenous injection of electrargol.

Prolonged Pneumococcemia.—Turrettini relates a case of this affection in a young nursling in which the pneumococcus persisted in the blood for 180 days. The onset of the infection was violent and oxygen and camphor were administered. There was no frank pneumonia but several crises of fluxion to the upper lobes with cyanosis. Worthy of mention is the formation of abscesses in the punctures of the hypodermic needle which may have acted as counterirritation. During the entire summer the temperature showed fresh accesses at intervals of from a few hours to seventy-two hours. In the autumn there was an inversion of this movement, the febrile periods becoming longer and the afebrile periods shorter in the same ratio. Finally when winter arrived the patient settled down to a steady subfebrile temperature up to the time of defervescence and sterile blood.

The Open Window in the Treatment of Tuberculosis.—Sabourin mentions the great hostility of the public to the open window treatment. Apparently it is necessary to compromise with the patient's relatives on this score. There is of course no objection to airing the room while it is empty. The windows should be closed when the patient returns, to allow him to undress, and the bed should be as far as possible from the open window, with its foot turned toward the latter. The window should be wide open after the patient is abed. The author has had windows open in his practice for 30 years in all febrile affections and at an early period extended the practice to all sicknesses and has never seen any inconvenience caused. However, it is advisable to establish tolerance by raising the window but a short distance the first night and increasing it gradually. There are various devices to be used in cold weather to keep the wind from blowing on the patient, chief of which is a screen to be placed at the foot of the bed.—*Journal de médicine et de chirurgie pratiques.*

Book Reviews.

THE MEDICAL RECORD VISITING LIST OR PHYSICIANS' DIARY FOR 1919. Revised. Prices, $1.50 to $2.25. New York: William Wood and Company.

THIS well known Visiting List is issued early and contains the customary blanks for patients, with special blanks for consultation practice, obstetric engagements and practice, vaccinations, register of deaths, addresses of patients and nurses, and cash account. There is much miscellaneous information at the beginning of the volume. This visiting list has long enjoyed a well deserved popularity, not only on account of its excellent arrangement and good paper, but also because it is of convenient size and is handsomely bound.

ORAL SEPSIS IN ITS RELATIONSHIP TO SYSTEMIC DISEASE. By WILLIAM DUKE, M.D. Ph.B., Kansas City, Mo. Professor of Experimental Medicine in the University of Kansas School of Medicine: Professor of Medicine in Western College, etc. Price, $2.50. St. Louis: C. V. Mosby Company, 1918.

CHAPTERS are devoted to pyorrhea alveolaris and alveolar abscess as the two leading causes of dental focal sepsis, to metastatic infection proper and the relation of oral sepsis to non-related forms of infection, on the purely toxic effects of local sepsis and the relation of dental sepsis to headaches. The work is illustrated with 170 radiograms. Two questions which require answers are "is the book original or only a compilation?" and "is oral sepsis overemphasized as a cause of morbidity?" While the author freely acknowledges his indebtedness to writers on the subject, the radiograms, laboratory reports, etc., all show plentiful evidences of first hand work. As for the second question the author appears to be conservative—for example he states that dental sepsis ranks theoretically as a very frequent cause of ill health. Again he states that therapeutic results based on treatment of dental sepsis as a cause of disease "are often disappointing." We therefore believe the author to be a safe guide in this difficult contemporary problem.

SUI DISTURBI TROFICI OSSE| CONSEGUENTI ALLE LESIONI TRAUMATICHE DEI NERVI PERIFERICI. Dott. E. TROCELLO. Maggiore Medico nella R. Marina, Aiuto di Clinica. Supplemento agli *Annali di Medicina Navale e Coloniale*, vol. 1, fasc iii, 1918. Roma. Stabilimento Tipografico della Societa delle Cartiere Centrali, 1918.

THIS volume comprises 38 radiographic plates with about double that number of original photographs, practically all of the hands and feet, and of the paws of experiment animals, their object being to visualize the osseous changes which result from traumatisms of the peripheral nerves. The text describes all of the trophic alterations in the limbs with special emphasis on the skeletal changes. The causes of these injuries are various, including projectile wounds, freezing, immobilizations, vascular injuries, etc. The alterations are summed up by the word atrophy. The great bulk of the book consists of case histories—31 in all—and protocols of animal experiments.

ANIMAL PARASITES AND HUMAN DISEASE. By ASA C. CHANDLER, M.S., Ph.D. Instructor in Zoology, Oregon Agricultural College, Cornwallis, Oregon. New York: John Wiley and Sons, Inc.

THIS book is addressed to a wide audience. The author says: "It is the aim of this volume to present the important facts of parasitology, as related to human disease, in such a manner as to make it readable and useful not primarily to the parasitologist, but to the public health and immigration service officers; to the physicians who are concerned with something more than their local practice; to teachers of hygiene, domestic science or other subjects in which health and preventive medicine are important; to college and high school students; to the traveler; and to the farmer or merchant who is interested in the progress of science and civilization." Readers who belong to the class of college or high school students, travelers, farmers or merchants will find in this book the important facts of parasitology as related to human disease presented in a readable manner. The book is divided into three sections; the first deals with protozoa, the second with "worms," and the third with arthropods. There are numerous illustrations, and the volume includes a valuable list of "sources of information."

The author seems to have been particularly unfortunate in the physicians whom he has met and with whom he is acquainted. He tells us that "Many physicians at the present time have little knowledge of venereal disease" (page 58); and (page 4) "Popular ignorance of diseases, even such common ones as malaria and syphilis, is nothing short of appalling. This ignorance is by no means confined to the poorly educated masses; it is widespread among educated, college-bred people, and, piteous as it may seem, *is characteristic of many professional men, among them even physicians bearing good reputation.*" (Italics ours).

CONCERNING SOME HEADACHES AND EYE DISORDERS OF NASAL ORIGIN. By GREENFIELD SLUDER, M.D. Clinical Professor and Director of the Department of Laryngology and Rhinology, Washington University Medical School, St. Louis. With 115 illustrations. St. Louis: C. V. Mosby Company, 1918.

THE object of the book is to show that many headaches and eye troubles, although attributed to other causes, have their origin in the nasal organs. Dr. Sluder presents his arguments for this point of view in coherent and well marshalled order. The first chapter deals with vacuum frontal headaches with eye symptoms only and affords a demonstration that the "astheriopics" are not eye cases but nose cases of a kind not yet understood. The subject of headaches and eye disorders arising from nasal diseases or disorders is discussed from all standpoints. Dr. Jonathan Wright presents an introduction to the pathological anatomy and he as well as other authorities are quoted and referred to in support of Dr. Sluder's contentions. The book is adequately illustrated.

HYGIENE AND MANAGEMENT OF PREGNANCY. A Booklet Concerning the Care of the Prospective Mother. By MORRIS J. KROHN, M.D. Attending Physician St. Anthony's Hospital, Denver, etc. Price, 35 cents. Denver: Published by the author, 1917.

THIS booklet bound in paper is written entirely for the prospective mother. The 32 pages comprise 19 chapters each of which deals with the hygiene of pregnancy or the expected confinement. Under the latter head are fixation of the date, when to arrange with the accoucher, collection of urine, the lying-in room and other preparation for labor. Under hygiene we find such subjects as exercise, diet, sexual life, clothing, care of breasts, care of bowels, etc.

PRACTICAL GUIDE TO DISEASES OF THE THROAT, NOSE AND EAR FOR SENIOR STUDENTS AND JUNIOR PRACTITIONERS. By WILLIAM LAMB, M.D., C. M. Edin., M. R. C. P. Lond. Honorary Surgeon, Birmingham Ear and Throat Hospital. Fourth Ed. Price, $3. New York: William Wood & Company, 1918.

THE first edition of this work, which appeared in 1905 was styled a "Guide to the Examination of the Nose, Throat and Ear." The volume has now become a full fledged textbook, but the word Guide has been retained in the title. The number of pages is 372 and the number of illustrations 61. The latter, which contain little that is hackneyed, impress us as well chosen and of good teaching values. The book is practical from cover to cover, with all the terseness of a manual for a technician.

HOW SHALL I TAKE EXERCISE AND SET-UP? A Physician's Analysis of the Why and Wherefore, etc. By SAMUEL DELANO, M.D. Price, $2. Boston: The Four Seas Co., 1918.

THIS volume is illustrated with 35 photographs showing free gymnastics. It is a personal book and there is no allusion to the writings of others in the same field, as Lagrange, Sargent and McKenzie. We find few actual facts concerning the physiology of muscle and exercise but the author discounts such omission in his preface. He devotes chapters to exercise in general, breathing, games and sports, set up, round shoulders, exercise for invalids, fat and cognate subjects, and appends a full description of the special exercises, which form the subject of the illustrations.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 7, 1918.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THE program for this meeting was furnished by the foreign delegates to the American College of Surgeons.

Dr. WALTER B. JAMES, in opening the meeting, stated that this was an exceptionally interesting evening on an exceptionally interesting day. (Applause.) The outside enthusiasm which reached our ears must be echoing around the world; probably there were very few places in the world that were not making such noises as we were listening to. We all knew deep down in our hearts what our Allies had suffered during the last four years and what they had suffered willingly. We also realized what would have happened to us if their lines had broken down. Those of the profession who were in khaki and also those who had stayed at home knew the part that medicine had played in winning the war. They knew what the mortality from diseases had been in previous wars in comparison to that of the present war, and that it would have been almost impossible to have endured the long suffering imposed by the present war had it not been for the work of the medical profession. The surgeon liked to feel that, though he had not carried a gun, he had carried a scalpel and had a hand in the winning of the war. We had with us this evening a group of men who stood at the top of our profession on the other side. It was a pleasure to feel that the war had drawn the members of the profession closer together, not only those who were in the war, but those who were not able to be at the front. We had learned to love the French, the Italian, and the Belgian physicians as our own brothers and it meant much to us to have these men on the platform this evening to talk about some of their most vivid experiences.

Dr. James said that they had found it necessary to take liberties with the program and had decided to devote a good part of the evening to the discussion of the "Modern Military Aspects of Lung Surgery." Many of those present could remember when they had dreaded to approach the pleural cavity and some of them remembered when the contents of the abdominal cavity were handled with fear, whereas they were now handled with impunity. It now came as a surprise that the surgeon could do with the contents of the thoracic cavity much the same as he did with those of the abdominal cavity. We had with us this evening men who had done as much as any in the development of lung surgery.

Major PIERRE DUVAL of the faculty of the University of Paris and Consulting Surgeon of the French Army addressed the audience in his native language and was interpreted by Lieutenant-Colonel Raffaele Bastianelle. He declared that surgery had had the greatest evolution during this war. This statement was especially true of surgery of the chest. Whereas we formerly considered the chest inaccessible to surgery, we now dealt with the lung in the same way as with the organs of the peritoneal cavity. The evolution of thoracic surgery has occurred through three stages. At first they had treated wounds of the chest by expectant therapy, but it was seen that the mortality was very high, 40 or 50 per cent. They had tried after this experience to treat chest wounds according to the same principles which they had found useful in the treatment of other wounds in other parts of the body. In the French Army these principles had been applied and perhaps they had been applied less extensively in other armies. The application of the principles for the treatment of wounds in other parts of the body included the excision of all injured tissue and primary closure of the wound. After this treatment primary union with good results might be expected in from eight to fifteen days. These principles could be applied to lung wounds. They had acquired a technique which permitted them to have access to the lungs and to treat them in a very safe way. The evolution in chest surgery had been hindered by the idea that operations on the lungs could not be undertaken except by the use of special physical apparatus which was supposed to make these operations safer. Instead of this they had adopted the method of opening the chest widely and of not fearing the production of artificial pneumothorax. They did not fear to pull out the lung and to excise or suture it, just as they did the intestines, which one could take out, subject to a surgical procedure, and put back again. Having this technique, they had treated lung wounds under the following conditions: 1. When death threatened within a few hours from severe hemorrhage. 2. When sufficient damage had been done to the lung to threaten the subject with asphyxia. 3. In wounds recognized as not so dangerous, but which it was feared would become infected. For the cases of severe hemorrhage the rule had been to open the thorax, to check the hemorrhage, and to suture the wounds. These cases had had a very high mortality, 40 per cent., and that meant that they saved 60 to 65 per cent. of all the cases of severe hemorrhage. In a chest with lung lesions they had learned that the chief complications came from infection or from a foreign body lodged in the wound. In such cases the first thing to do was to remove the foreign body and to treat the wound according to the general principles of treatment of war wounds, that was by excising the margins of the wound, suturing the wound, and closing the chest wall. The general result that they had obtained with this method might be summarized as follows: Previous to the adoption of this method for the treatment of lung wounds in army hospitals the general mortality was 25 to 30 per cent., while since the adoption of this method it had been lowered to 9 per cent. The total revolution in chest surgery was based on three principles. These were, first, a wide opening of the thorax wall which produced complete pneumothorax and taking hold of the lung and treating the wound as elsewhere in the body. They had found that operative pneumothorax had no danger in itself, as was shown by the work of Crile, and as they had learned from their practical experience in war surgery. The technique consisted in making a large opening in the chest wall removing a section of rib and putting in the rib spreaders so as to have easy access to the thoracic cavity. This was the technique introduced by Dr. Willy Meyer. The second principle was to seize with the forceps each lobe of the lung, consecutively, pull it down, inspect it and treat it according to the special indications. The third principle was that the chest wall must be closed completely, no drainage being inserted. The pleura, thoroughly cleansed, would take care of itself. The results of this method were very good and very encouraging. The speaker in his last thirty-three operations had lost no case. Furthermore, the cure that was obtained by this method was of a quality superior to that obtained by any other method in that it secured a complete restoration of function. The lung could expand completely and the man came out of the hospital with perfect function of the lungs and was a new man.

Major Duval illustrated his address with lantern slides, demonstrating this method of opening the chest, treating severe hemorrhage, removing foreign bodies, and closing the chest wall. Slides also showed the results in a number of typical cases.

Lieutenant-Colonel RAFFAELE BASTIANELLI, Professor of Surgery of the Royal University of Rome and Consulting Surgeon to the Armies of Italy, said he would try to conduct his hearers along the road that was taken by Major Duval, since the principles that he had expounded were sound not only for the treatment of war wounds, but for civilian practice as well. In Italy war surgery was the same as in other countries. Custom, tradition, and the rules of military practice had during the early part of the war prevented them from interfering with chest wounds. In fact military regulations prohibited operating on wounds of the chest in the early part of the war, but the mortality was so heavy under the expectant plan of treatment and infection such a common cause of death in these wounds that they began to treat them by the methods which Dr. Duval had described, that was, by removing fragments of shell, bullets, or other foreign bodies, and suturing the wound. It was important that they should have a union that was airtight. They

had found that chest wounds could be divided into two categories, one in which the chest wound was closed and did not permit air to come into the pleural cavity and the other in which the wound permitted the free entrance of air. The complete operation as described by Major Duval was easy if the chest wall was widely opened, because one could then inspect the contents of the thoracic cavity. The difficulty was with the closed chest wounds in which it was difficult to prevent infection. In the hands of men like Major Duval and Colonel Gask these operations were easy, but they were not easy for everybody. First, as to the lung wounds themselves—these might be of three varieties: 1. Lung wounds were sometimes perforating and there might also be contusions. This class of wounds he would not consider at the present time. A lung wound might bleed so extensively that the man arrived at the first aid station in such bad condition that he was not sent back to the hospital. 2. There were wounds with moderate hemorrhage. 3. There were wounds with concealed or silent hemorrhage. In these the man came in with the signs of a lung wound and a very small amount of blood in the pleural cavity. The following day there would be a larger amount of blood and exploratory puncture would reveal the fact that there was a concealed hemorrhage. These cases occurred much more frequently than was suspected, the bleeding being slow because of the physiological factor, the negative pressure. Because of the continuous expansion and contraction the lung was never immobile and this was not favorable to closure of the wound. However, one often saw hemorrhages into the pleural cavity which were cured by nature. The factors which stopped the hemorrhage in these cases were thrombosis, or blood, or air, in the pleural cavity. It was not admitted that the blood was a very favorable factor because even 2000 or 2500 c.c. of blood in the pleural cavity did not put the lung in a condition of immobility, as the liquid could not follow the expansion of the chest wall and lung as did air. Since they had been opening the thoracic cavity it was a very familiar sight to see the lung collapsed to the size of a hand, the blood vessels being scarcely perceptible and the hemorrhage very slight. The production of artificial pneumothorax checked hemorrhage and if the lung was immobilized a condition was produced which was essential in the treatment of any wound. If we allowed nature to treat these cases there was often extensive clotting of the blood and as the lung expanded and contracted it was forced to take a position which did not correspond to its natural anatomical position and adhesions then formed so that the lung could never again take its normal position, with the result that there might be mediastinal deformity and the heart might be displaced, and the lung never recovered its normal function. As long as there was air in the pleural cavity the lung was collapsed and movable and in time the lung expanded, and even if slight adhesions were formed they were not unfavorable to recovery of function. In the open cases the course was clear, but when a case presented a closed chest and a wound, one had to remove the blood and introduce air. This was the artificial pneumothorax of Dr. John B. Murphy. Again it was to be remembered that it might be dangerous to remove the blood from the pleural cavity if air was not introduced. As to their results, they had had 370 cases of chest wounds brought to a certain hospital 290 of which were penetrating wounds of the lung Of these 206 were closed wounds and 84 were open chest wounds. These 206 were treated with artificial pneumothorax and only seven died, which was a very favorable showing for closed chest wounds. Of the 84 with open chest wounds 19 or 22 per cent. died. (They did not have blood transfusion at the time.) Eight of these died within twenty-four hours, or on the following day. Of the remaining 76, 11 died of empyema, and 4 of septicemia. The empyema was due to the open chest and plugging with rubber bags. Since they had been doing the airtight sutures, they had 35 cases with 2 deaths, which meant a mortality of 5 per cent. This meant that artificial pneumothorax was worth while trying.

Colonel Bastianelli gave a lantern slide demonstration of his apparatus which could be used for drainage and also as a suction apparatus in cases of empyema. By the use of this apparatus cure was effected much quicker than by the old method of open drainage tubes. Slides were also shown demonstrating the method of using an apparatus which was so devised that it could be used both for washing out the pleural cavity and for introducing air.

Sir THOMAS MYLES, formerly President of the College of Surgeons of Ireland, spoke of some of the later phases of lung surgery in this war. The British had not had at their front a Major Duval, a Colonel Gask, or a Colonel Bastianelli, men who had had experience in the early treatment of lung wounds, and as a result they had gotten back in due time, and the Americans would also get back, men who had injuries of the chest or who had a projectile or shell fragments still embedded in the lung. That these men escaped the high class surgeon and reverted to the surgeon at home was due to the exigencies of war time. A large number of these men reached base hospitals and when they did they came in a variety of conditions. Some came with a bullet in their lung and said it did not give them any trouble, but these were very rare. The majority who had had chest wounds had physical signs or they did not. Those who had physical signs manifested them by hemoptysis or purulent expectoration. Those who did not have physical signs complained of shortness of breath, pain in the side, and were unequal to sudden effort. They had to deal also with men who, in addition to these troubles, had vivid imaginations; they had, as he termed it, "a bullet in their minds." They were likely to attribute every slight or imaginary ailment to the presence of a bullet in the chest. The bullet might be in the chest, but the shadow of the bullet was in the mind, and in handling these cases it was necessary to get the bullet out of the mind as well as out of the chest. There were two schools of thought as to how to approach this problem of getting the bullet out of the chest. The one was that represented by Sir Berkeley Moynihan, which might be called the statutory method, and the other was that represented by Major George Gray Turner. In the development of the statutory method the reasoning was something like this: Theoretically, the examination of the chest was made by the *x*-ray man. He told the surgeon that the bullet or shell fragment was so many centimeters from a certain point and so many centimeters from another point; but when one came to look for the bullet at the point designated it was like hunting a needle in a haystack. You might add to the *x*-ray, auscultation, percussion, and palpation, and you would still find that there were many uncertainties involved. It had been the speaker's experience that one very rarely found that the opinion expressed in writing as to the location of a foreign body corresponded to the facts exposed at operation. There was still a hiatus in our methods. He simply called attention to this in passing in the hope that the young medical student would recognize that here was a field for future discoveries. The surgeon who started to find a foreign body in a lung at the present time embarked on an unknown sea. For this reason he favored the statutory method, which consisted in making an incision along the fourth rib, starting at the lateral line of the sternum and extending for five inches in a line corresponding to the horizontal border of the pectoralis major muscle; through this incision the rib could be lifted up after dividing it at the costal cartilage. The periosteum of the rib must be left with the pleura, because the pleura was very delicate and would not carry a suture, but the pleura and peritoneum together would carry the suture and remain water tight and resistant. When the pleura and periosteum were opened either the lung collapsed or it did not. If there were no adhesions it collapsed; if there were adhesions it collapsed as far as possible; if there were very extensive adhesions it did not collapse at all. If the lung collapsed it presented an entirely different picture from that to which we were accustomed. When we saw a lung inflated it filled the whole thorax, but when we saw it collapsed it had shrunken to a very small compass and was bloodless. When it was in this condition one was dealing with a mobile viscus that could be handled with perfect freedom and without the need of special apparatus. In cases in which there were adhesions it was advisable to break them down,

because if left they were likely to cause pain and shortness of breath. If the pulmonary and parietal pleura could be kept separated for a few days the adhesions would not be likely to reform. Having broken up the adhesions the next step was to get rid of the blood in the pleural cavity and to thoroughly dry the thorax. The lung could then be dropped back, wounds sutured, and the rib replaced. No drains were used and hence it was necessary to cleanse the pleural cavity very thoroughly. The attempt was made to keep the pulmonary and parietal pleura apart from forty-eight to seventy-two hours, but they had not as yet developed a thoroughly scientific method of doing this. Only when one was very sure just where the bullet was located was he justified in cutting directly down to where it seemed to be. Another point to be brought out was that trying to reach a bullet or shell fragment through a very small incision made it impossible to deal with all the conditions that one might meet. For these reasons the statutory method of approach seemed preferable.

On motion, a vote of thanks was unanimously accorded the speakers of the evening.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, October 23, 1918.

THE PRESIDENT, MAJOR FRANK C. HAMMOND, IN THE CHAIR.

The Value of Active Immunization with Vaccine Virus Against Influenza.—Dr. JOHN H. KOLMER, in speaking upon this subject, desired that his remarks be interpreted purely as a preliminary statement. He said that by most bacteriologists the disease was regarded as due to the influenza bacillus. In the work of Dr. Kolmer and his associates, however, considerable difficulty was being experienced in isolating this bacillus. In their findings the streptococcus seemed to predominate. The vaccine prepared by them contained not only the influenza bacillus, but the pneumococci, particularly Types II and IV, which they had found to predominate in the sputum and in the pulmonary lesions, also many strains of streptococci and of *Micrococcus catarrhalis*. Certain serological investigations, he said, were under way to determine the more exact relationship of these organisms to the disease. In a preliminary way he would state that evidence was at hand indicating that the streptococcus and *Micrococcus catarrhalis* were also concerned in the pathology of the infection; possibly, not as primary agents, but as secondary factors of considerable importance. That the resistance of the patient might not be reduced small doses of the vaccine had been given at intervals of three days until three injections had been made. A distinction, in Dr. Kolmer's opinion, should be made between the practical value of commercial stock vaccine, and those prepared from organisms from the present epidemic. Reports from the vaccine prepared by Dr. Kolmer and his coworkers had been generally favorable; such were, however, to be accepted for the present with a good deal of reserve. While the administration of the vaccine at intervals of three days seemed to protect a certain percentage of individuals against influenza, Dr. Kolmer stated that it did not confer absolute immunity. Reports by direct correspondence from other cities were of similar nature. It might, therefore, be tentatively stated that the vaccine was worthy of trial, particularly in institutions and hospitals. Concerning treatment of the disease, even more conservatism was to be maintained. While the majority of clinicians who had used the vaccine were of the opinion that it cut short the febrile period, Dr. Kolmer was not prepared at this time to make any definite statement. It was his belief that the vaccine was well worthy of trial in the prevention of disease, that it might even prove of distinct benefit in treatment, provided it was given early and in small doses. He believed that the dosage bore important relation to the results.

The Physical Findings in Pneumonia Complicating Epidemic Influenza.—Dr. M. HOWARD FUSSELL, describing the simple case of influenza said that it began with cough, pain in the legs and back, depression, temperature of from 98° to 103° for a day or two, dropping back to normal, then rising and again dropping. In cases in which the temperature, after having been normal for three or four days rose to 103° and 104° and remained at that point for two or three days, lung involvement might be expected. In hospital and private work he had been impressed with the fact that one of the characteristic facts in regard to severe pneumonia was that the patient with influenza had been well for two or three days, and then developed pneumonia. This had been borne out in the experience of nurses in two hospitals in which Dr. Fussell had service. In one hospital eighteen out of twenty-four nurses had been sick with influenza; two or three of these developed pneumonia and all recovered. In another hospital sixty-five nurses had influenza, three had pneumonia, and all recovered. This favorable result was not, in his opinion, because of any specific treatment, but due to the fact that the instructress of nurses had been told that immediately upon the appearance of the first symptom of influenza the nurse should be put to bed and kept there until the attack was entirely over. In the pneumonia developing in a patient who had been kept in bed and whose temperature had been normal for three or four days, then became elevated, the condition seemed to be localized; there was observed, first: dullness over the affected area, with crepitation; in a day or two large moist râles were heard; then when the individual was almost well there was blowing breathing. In the cases of pneumonia beginning suddenly like lobar pneumonia the patient soon became cyanosed; the pulse was not very rapid until the very end, but there was evidence of an overwhelming toxemia, and in this form of pneumonia all forms of treatment had failed. It was to be regretted that careful scientific work during the epidemic was practically impossible. This was no one's fault, being due to the few available for help and so many being ill. The duration of the physical signs in the chest after recovery of the patient was to be noted. In one patient discharged and sent to Atlantic City these signs had been about as pronounced as when the temperature had come to normal. Another observation was that of the large continuance of blood in the sputum. The menses were apt to appear at an unusual time; and nosebleed was common. In Dr. Fussell's experience the mentality was preserved even in the patients dying from the intense toxemia. In the cases seen by him only two persons were over fifty years of age; in only four had empyema developed. There had been three or four cases of parotiditis; these patients recovered under the ordinary surgical treatment. In 320 cases of influenza there had been ninety deaths; this did not mean the cases of pneumonia, many of these having died within twenty-four hours. He had had only four recoveries in pregnant women.

Report of Eight Cases of Acute Appendicitis Complicating Epidemic Influenza.—Dr. MOSES BEHREND advised operation under nitrous oxide gas and oxygen anesthesia when the differential diagnosis between chest and abdominal conditions was impossible. In the event of a mistake the course of the pneumonia would not be altered. The one sign which more than any other differentiated pneumonia from appendicitis was, in his experience, rapid breathing with playing of the alæ of the nose. This was absent in acute appendicitis. It had been a constant observation that appendicitis occurred in increased frequency after epidemics of influenza. Lichtenstern was quoted as believing the condition a typhilitis rather than one of true appendicitis, that exceptional cases of true appendicitis might occur, and that coincident appendicitis simply accompanied an attack of influenza. In only one of the cases reported by Dr. Behrend was there history of several attacks of appendicitis; neither could he subscribe to the theory of typhilitis. Such cases, he believed, were primarily appendicitis, the inflammation spreading to the cecum. Of the eight cases reported three had been operated upon and recovered. In the other five operation was not done because, from the number of râles present, it was feared that pneumonia would result; these râles had been indicative of an extensive edema rather than of pneumonia, and in these the appendical symptoms gradually subsided. The appendicitis had developed at the height of the attack of influenza.

The Nasal Complications of Epidemic Influenza.—Dr. G. W. MACKENZIE observed that practically all our present knowledge of sinus disease dated from the works of Zuckerkandl and Hajek following the last world epidemic of influenza occurring in 1889-1890. Septal deflection was mentioned as one of the most important predisposing causes of sinus disease. The intranasal complications of epidemic influenza should be guarded against by treatment directed to the systemic condition. There should be avoidance of local applications to the nose and throat, no antiseptic being sufficiently strong to destroy a virulent strain of the *Bacillus influenzæ* which would not injure the mucous membrane. He emphasized the importance of breathing through the nose, and through both sides simultaneously. The use of alcohol was to be avoided. In fatal cases of influenza with cerebral complications suppuration of one or more sinuses was regarded as an important factor. In acute sinus disease drainage was regarded by the rhinologist as conservative treatment. Results so far observed had been better from surgery alone than from vaccines alone.

Dr. RICHARD C. NORRIS attributed the extraordinarily high mortality of influenza in pregnant women to the overwhelming toxemia present at a time when their resistance was reduced by the process of pregnancy. Reference was made to the arrangement of wards and rooms at the Preston Retreat, making isolation of patients easily possible. The few cases occurring in the Retreat had been put at once under the care of special nurses and all contact with the rest of the house severed. No deaths had occurred. One woman brought in from another hospital where no room had been available had a pulse of 138-140 and was cyanotic. Recovery took place and the woman did not miscarry. Whether the patient had pneumonia Dr. Norris could not determine; temperature was 104°; respirations, 32; pulse, 138. There was not a sign of pneumonic change that he could detect. Contrary to the experience at the Preston Retreat was that at the Methodist Hospital. Within a week ten women with pneumonia had been brought in, of whom nine died, and out of the entire group there were but three living children. Of influenza cases not complicated by pneumonia Dr. Norris had seen five in his private practice. All had recovered; three had living children. In many cases of influenza with pneumonia he had been consulted upon the advisability of induction of labor. His position had been that a woman so handicapped had better not be placed under the additional strain of falling into labor. In two earlier instances in which the patients were borderline cases he had induced labor and the patients had died. Since that time he had declined to follow this course of treatment. In two cases presenting no sign of pneumonia he had induced labor because of the toxemia of pregnancy. In multiparæ, some of whom had been exposed to the most virulent type of influenza and others showed slight temperature, he had terminated pregnancy. All had made good recoveries and the children lived. This was not, however, justifiable in primiparæ.

Lieutenant RUSSELL S. BOLES said that of the cases observed in the camp hospital marked drowsiness was the most noticeable feature. The onset of the infection was sudden, the period of incubation being apparently twelve to forty-eight hours. There was lack of coryza and sneezing. Harassing cough was present, also epistaxis. Fever of 101° to 103° was almost invariably noted. There was severe lumbar backache attributed to the intense degree of nephritis; also a peculiar cyanosis like that following the use of acetanilid. The abdominal pain confused the condition with appendicitis. Of the 525 cases of influenza there were 168 cases of pneumonia with 48 deaths. In the apparently early recoveries emphasis was placed upon the importance of not allowing the men to return to the training camp until cure had been established. The complication of nephritis had sometimes been very severe. Otitis media was present in ten or fifteen cases; four suppurated. While there were many so-called mastoiditis cases, none had proceeded to suppuration. The gastrointestinal complications when severe were regarded as unfavorably influencing prognosis. Pleurisy and empyema were relatively uncommon. Immunization with vaccine, while not absolutely preventive, was regarded as of some value. In prophylaxis the greatest reliance had been upon the use of the mask.

Dr. THOMAS C. ELY, in outlining his treatment of influenza patients, said that he first cleansed the intestinal tract with calomel and a saline purge. This was immediately followed by the active administration of the alkalies used to combat acidosis—bicarbonate of soda, citrate of potash, and the calcium salts in the form of lime water. To every patient was administered a teaspoonful of bicarbonate of soda to a pint of lukewarm water every four hours by enema. He had given by the mouth bicarbonate of soda and citrate of potash every hour alternately. The calcium salts he had given in the form of lime water one-third and milk two-thirds. To patients with fulminant attacks of vomiting and severe headache unable to tolerate the potash salts he had given only the sodium bicarbonate mixture every hour and the soda enemas. He had used neither aspirin, coal tar series, heart depressants, serums, nor vaccines. In his opinion these patients so desperately ill could not have recovered without the basic treatment by the alkalies upon the acidosis theory. When tolerated he had given quinine, 4 grs., morning and evening. He had recommended quinine in connection with the soda salts as a preventive. He had also given strychnine and quinine every four hours during convalescence. He believed that early sweating by hot drinks and the giving of water only during the first twenty-four hours were beneficial procedures.

Dr. S. SOLIS COHEN regarded the use of mixed bacterins as highly scientific, useful, advisable, and necessary. He believed that they prevented the incidence of influenza and pneumonia. In instances where such incidence was not prevented they rendered the attack much less severe. They seemed also to give some protection against the streptococcus, the most deadly of all the bacteria concerned. He would hesitate to give the mixed bacterins in the presence of influenza and streptococcic toxemia at a late stage. When, however, they could be given early he would place as much reliance upon their efficacy as upon the use of mercury in syphilis, or of quinine in malaria. He agreed with Dr. Ely upon the importance of the early alkalinization of the blood throughout every attack of pneumonia, of influenza, and of mixed infection. In pregnant women he was convinced that the administration of aspirin and phenacetine was responsible for many deaths.

Dr. LIDA STEWART COGILL said that the present epidemic had been in her experience very fatal to mother and child. At the Woman's Hospital seven prenatal cases had died. The patients who had had influenza before coming into the hospital had done well and the babies had lived. With those developing pneumonia the babies were dead before they were born.

Dr. WILLIAM EGBERT ROBERTSON remarked upon the small number of colored persons who had contracted influenza. He thought it the general experience that this race had been rather exempt. Following early intravenous administration of bacterins, particularly of the sensitized bacterins, his results in the present epidemic had been little short of brilliant. A matter of surprise to him had been the withholding of food from patients with elevated temperature. It was his opinion that if a patient were fed to his ability to take food his opportunities for recovery were enhanced.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Annual Meeting Held in Philadelphia, September 23, 24, 25, and 26, 1918.

(*Continued from page 880.*)

SECTION ON MEDICINE.

First Day—Tuesday, September 24.

Pneumonia.—Dr. W. J. K. KLINE of Greensburg laid importance upon the trained ear in the diagnosis of this disease. Active diaphoresis was indicated, which might be produced by external moisture and heat and by internally creating active secretion of the internal organs, this to be followed by warm potations

and a saline cathartic. Veratrum viride was recommended in the presence of arterial tension. The routine use of veratria was discouraged. The tincture should be used in doses of eight to ten drops every two hours, the dose to be reduced or increased as required to bring the pulse rate down rapidly to 80 or to 60 beats, until nausea appears, when the rate would be lowered. This rate, to be maintained for from 24 to 48 hours, was an important factor in clearing up the congestion.

Dr. Charles Rea of York said that since the greater number of cases followed measles, therapeutics should be directed toward prevention. In the treatment of lobar pneumonia there should be avoidance of polypharmacy, in the form of drugs or bugs. Early digitalization was regarded favorably in that the patient might respond quickly to digitalis by the mouth should sudden necessity arise. Turpentine in enemas and stupes was regarded as the best means of combating abdominal distention. In the treatment of streptococcus bronchopneumonia there was little to offer beyond preventive measures and intelligent care.

Dr. S. Solis-Cohen of Philadelphia confessed to a change of feeling regarding the value of mixtures of stock bacteria since having observed the work of Majors Smith of Uniontown, Dare, and Bergey of Philadelphia. They had prepared a vaccine from streptococci, staphylococci, *Micrococcus catarrhalis*, and four types of pneumococci, after the use of which the mortality was less than 6 per cent.

Some Recent Results of Coordination of Laboratory and Clinical Researches in Pneumonia.—Dr. S. Solis-Cohen of Philadelphia gave a report of results of coordinated research by Drs. Kolmer, Heist, Steinfeld, Weiss, and himself, showing the chemotherapeutic activity of cinchona derivatives against the pneumococcus *in vitro* and *in vivo;* the inferiority of optochin to ordinary quinine compounds in human pneumonia; pneumonia poison in the human lung; the inhibiting effect of quinine on this and pneumotoxins; the Lacy-Heist method of studying immunological power of whole circulating blood; immunity of certain individuals and birds against pneumonia; bacterins (vaccines) and quinine mouth washes as preventives.

Dr. David Riesman of Philadelphia believed that in no disease was the close cooperation of laboratory workers and clinicians more opportune than in pneumonia, oratory examinations. The man not educated in the climate. Its problem was to be attacked more from the point of prevention than had obtained hitherto. That a healthy carrier might spread the disease was a discovery of the utmost importance.

Dr. George D. Heist of Philadelphia said that in their research work they had found that the serum of a man receiving five and sometimes ten grains of quinine dihydrobromide every three hours over a period of a number of days killed pneumococci with great regularity after an exposure of 24 hours. The bactericidal element in the serum was proportionate to the quantity of quinine received. The dihydrobromide was the most active salt.

Laboratory Methods, Their Value and Practicability in General Medicine.—Dr. M. Howard Fussell of Philadelphia made a plea for accurate diagnosis by history taking, thorough physical examination, and routine laboratory exminations. The man not educated in the more modern and accurate diagnostic methods should associate with himself a young man to do this routine work for him. Dr. Fussell exhibited a well arranged kit with facilities for making diagnoses in conditions met in the work of the general practitioner.

Dr. Henry Rhea Douglas of Harrisburg cited a case demonstrating the importance of diagnosis upon the principles enunciated by Dr. Fussell. In a boy of nine years, treated for an eye condition accompanied by anemia and glandular enlargement, subsequent history taking suggested a Wassermann test, which gave a reaction of four plus.

Dr. H. W. Mitchell of Warren emphasized the value of laboratory study in diagnosis of patients admitted to the hospitals for the insane.

Dr. Paul G. Weston of Warren urged the more frequent employment of lumbar puncture in diagnosis and the necessity of a chemical analysis of the blood to accompany the uranalysis.

Some Drug Eruptions.—Dr. M. B. Hartzell of Philadelphia said that while a large number of drugs produced eruptions, but relatively few affected all individuals; that the same drug did not always produce the same form of eruption. The iodides, usually causing an acneform eruption, might give rise to more serious disturbance; this was true also of the bromides. The hypnotics produced eruptions of varying character. Arsphenamine sometimes caused a violent dermatitis, with symptoms of nephritis. The possibly etiological factor of a drug should always be remembered in the presence of an unusual form of eruption.

Dr. Julius H. Comroe of York cited an idiosyncrasy to drugs mentioned to him by Dr. B. A. Thomas of Philadelphia, in the administration of 270 grains of potassium iodide three times a day in ascendng doses for almost three months wthout producing an eruption. The administration of three grains in another case had been followed by a most intense rash. Routine ascending doses were discouraged, it seeming to be wiser that each case should be treated as an individual entity, with diminution or interruption of the dose upon the beginning of an eruption.

The Place of the Medical Inspector in Preventive Medicine.—Dr. Clarence R. Phillips of Harrisburg said that contagious diseases were the diseases of childhood largely because of compulsory education, which brought children into close contact. The problem of prevention was distinctly one to be handled by the State. The instrument for protection in the scheme of the State Department of Health was said to be the county medical inspector. Parents should be educated and teachers instructed; stern measures might be required to enforce the provisions of the new school code pertaining to communicable diseases.

Dr. Wilmer Krusen, Director of Health of Philadelphia, claimed for the county medical inspector the cooperation of the public in eliminating preventable diseases. Quarantine would be unpopular until the family appreciated that the rights of the individual ceased where the rights of society began. Development of the conscience of the practitioner who saw communicable diseases in their incipiency was also, in Dr. Krusen's opinion, an essential in the eradication of preventable disease.

X-Ray Examination of the Heart and Great Vessels.—Dr. G. W. Grier of Pittsburgh had seen in *x*-ray examination only two cases in which the heart was unquestionably too small for the performance of normal function, being in each instance about the size of a baseball. The athletic heart was said to be often hypertrophied; the small "drop" heart was supposed to indicate predisposition to tuberculosis of the lungs. Dr. Grier had fluoroscoped one case of heart block. The slow, massive contractions of the left ventricle occurred about twenty times to the minute, while the rapidity of the contractions of the right auricle was extraordinary. He regarded the *x*-ray as of distinct advantage in determining size and contour of the heart. In the differential diagnosis of aneurysm of the aorta and solid tumors in the mediastinum both fluoroscope and radiogram were to be used.

Second Day—Wednesday; September 25.

The Problem of Combating Septicemia with Especial Reference to the Use of Arsphenamine.—Dr. Samuel R. Haythorn of Pittsburgh said that arsphenamine had been administered in 29 cases of proved septicemia, with 17 recoveries and 12 deaths. The treatment was found to be beneficial, when used early in septicemias, if they were associated with primary foci easily accessible to surgical interference. In endocarditis, and conditions in which secondary localizations had become firmly established, arsphenamine was disappointing because it did not affect the localized lesions on the heart valve, appearing to be effective only in the blood stream.

Dr. Harold A. Miller of Pittsburgh had used arsphenamine in 14 cases. In none were there any untoward symptoms attributable to the drug. It was his experience that puerperal sepsis presented no contraindications to the use of arsphenamine which were not also contraindications in syphilis or other diseases.

Dr. Grover C. Weil of Pittsburgh cited a case of staphylococcus septicemia in a compound fracture with

fluctuating temperature for five weeks with a drop of temperature to normal five days after administration of salvarsan and with disappearance of the staphylococci five days later.

Dr. HAYTHORN, in closing, observed that the increased leucocyte count was a constant find following the administration of arsphenamine. Results in the treatment of endocarditis were discouraging.

One Hundred Cases Treated with Autogenous Vaccines.—Dr. WILLIAM A. WOMER of New Castle classified results in 100 cases including arthritis, acne, abscess, boils, carbuncles, endocarditis, eye, ear, nasal sinus and other infections. Of the 100 cases 87 per cent. recovered completely. The most satisfactory results were obtained in infections of the skin and subcutaneous tissues. The results in respiratory conditions were not satisfactory.

Dr. WALTER D. BLANKENSHIP of Lancaster emphasized that while autogenous vaccines were not a panacea, in certain cases they were imperatively indicated. General lines of treatment as indicated should be used in conjunction with the vaccine therapy.

Physical Examination in the Diagnosis of Early Pulmonary Tuberculosis.—Dr. LOUIS V. HAMMAN of Baltimore stated that of one hundred men presented for examination at least seventy-five had pulmonary tuberculosis. Of the seventy with signs of pulmonary change only four or five would develop pulmonary tuberculosis. Nothing could be of greater importance than to distinguish between tuberculous infection and tuberculous disease. The physical examination in the diagnosis of pulmonary tuberculosis, he said, really obtained its value from the relations of all the other associated clinical facts. One exception to this statement was that the presence of definite moist râles limited to an apex was an almost absolute indication of pulmonary tuberculosis.

Dr. ELMER H. FUNK of Philadelphia agreed with Dr. Hamman that physical signs were valuable only as emphasized by the consideration of history and symptoms. Of far more importance was the determination whether the disease was clinically active or inactive.

Dr. CHARLES H. MINER of Wilkes-Barre regarded as the most important question the relation between the extent of the pulmonary changes not due to active disease and the probability of developing active disease under conditions of unusual exposure.

Dr. ALEXANDER ARMSTRONG of White Haven, while disinclined to criticise the work of the draft boards in any other than a constructive way, cited one instance, typical of many, in which a man who had been under treatment for pulmonary tuberculosis was told by the draft board that his lesion was healed, and who had been passed into the first class. Inside of two months the man had become a physical wreck.

Dr. THOMAS MCCRAE of Philadelphia regarded as of doubtful accuracy the view held by some that the man in the Army was not greatly exposed to infection. In the diagnostic points dwelt upon by Dr. Hamman he regarded as of first importance the fact that suspicion is aroused. It was then the physician's duty to exclude the possibility that tuberculosis was present rather than to take the view that the condition was, for example, nothing but bronchitis.

Dr. JOHN A. LICHTY of Pittsburgh asked whether Dr. Hamman meant by "pulmonary tuberculosis" a specific or a mixed infection.

Dr. HAMMAN, in closing, admitted the great difficulty involved in a discussion of physical diagnosis—one man, very experienced, might hear râles where he could not; make out dullness where he could not. To such a man râles and dullness would be entirely different things from what they would be to him. Replying to Dr. Lichty, he meant by pulmonary tuberculosis, specific infection with the tubercle bacillus.

(*To be concluded.*)

Tailor's Thimble in the Nasopharynx of a Child.—Schönfeld reports that up-to-date parents brought their six-year-old child to the local x-ray institute after the disappearance of a thimble. The lower food and air passages were clear and the object was found wedged in the nasopharynx.—*Correspondenz-Blatt für Schweizer Aerzte.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

THE STATE MEDICAL BOARD OF THE ARKANSAS MEDICAL SOCIETY.

Little Rock, May 14 and 15, 1918.

(*Concluded from page 838.*)

GYNECOLOGY.

1. When is a curettement indicated?
2. Give differential diagnosis between ectopic pregnancy and acute appendicitis.
3. When should a ruptured perineum be repaired, and why?
4. What conditions justify the removal of one or both ovaries?
5. Describe symptoms of a retroverted uterus. How would you correct this condition, describing operation?
6. Give treatment for acute pelvic cellulitis.
7. Give symptoms and physical changes occurring during menopause.
8. Diagnosis and treatment of specific vaginitis.
9. What complications may arise following condition in question No. 8?
10. Describe salpingitis; give treatment.

SURGERY.

1. Give symptoms and treatment of corneal ulcer.
2. Give causes, symptoms, and treatment of brain abscess.
3. State causes and give treatment of suppuration in antrum of Highmore.
4. Discuss the symptoms and surgical treatment of hyperthyroidism.
5. Give in detail the treatment for gunshot wounds of chest.
6. Discuss causes and give treatment for acidosis following surgical anesthesia.
7. Given a patient two days before laparotomy for interval appendectomy, state the laboratory tests you would make. Give in detail preparation of patient for said operation.
8. Give symptom, physical signs, and treatment of intussusception in children.
9. Give in detail the surgical management of a case of acute osteomyelitis of the tibia.
10. Discuss the management of open Pott's fracture.

HYGIENE.

1. What are the dangers of surface water and dug wells?
2. What measures must be used in crowded apartments to insure good health and prevent spread of disease?
3. What measures should be taken in a community to prevent the spread of venereal diseases?
4. Name some of the ill effects of school life on the health of children.
5. What would you consider the duties of a medical supervisor for a school?
6. What constitutes a first class eating apartment?
7. What are the dangers of using ice?
8. Give name and description of malarial mosquito.
9. Which is to be preferred, autogenous or stock vaccines, and why?
10. What is sewer gas? How does the inhalation of it in large quantities affect the system?

ANSWERS.

GYNECOLOGY.

1. *Curettage is indicated:* (1) For removal of placental débris, (2) in hemorrhagic endometritis, (3) in some forms of dysmenorrhea (membranous), (4) for diagnostic purposes, (5) in some cases of puerperal sepsis, (6) sometimes to check hemorrhage due to fibroids.

2. *Differential diagnosis between ectopic pregnancy and acute appendicitis:* Appendicitis in its onset and in its further course may very closely simulate a ruptured tubal pregnancy, but in appendicitis there are

none of the general and local signs of pregnancy. There is often a history of previous attacks, with intervals of complete or partial freedom from pain and intestinal disorder. The distress is almost always confined to the right side, while in ectopic pregnancy it is often referred to the median line or left side. In both of these conditions the pain appears suddenly, and may be intense; in ectopic pregnancy it may be momentary, while in appendicitis it usually persists throughout the attack. The sudden pallor and collapse frequently following immediately upon the rupture of a tubal pregnancy never occur in appendicitis. It is at this time that a most suggestive sign appears, *i.e.*, uterine hemorrhage accompanied by a discharge of decidual membrane. In such an event there can be no further consideration of appendicitis. Much dependence is placed upon the further finding of an enlarged soft uterus and an irregular mass attached to it at the side or lying behind the uterus. When doubt exists, the uterus may be explored with a curet and the scrapings examined for decidual tissue." (Findley's *Diseases of Women.*)

3. All tears should be repaired as soon as possible (unless there are contraindications). A primary operation is best, because the edges are fresh and can be approximated; little (if any more) anesthetic is wanted; the woman has to lie in bed, and therefore only one absence from household work is requisite; infection is less likely. In any case, operation may prevent rectocele, cystocele, prolapse of uterus, and general weakness, malaise, and disability.

4. *Indications for removal of one or both ovaries:*—Ovarian tumors (unless specially contraindicated), malignant degeneration of the ovaries, abscess of the ovaries, cirrhosis of the ovaries, and some cases of osteomalacia.

5. RETROVERSION OF THE UTERUS.—*Etiology:* Relaxation of uterine ligaments; increased weight of fundus; subinvolution; ovarian or other tumor pressing on front of uterus; distended bladder; peritonitis or cystitis; prolonged dorsal decubitus and tight bandaging in the puerperium. *Treatment:* Remove the cause, if possible; replace the uterus and keep it in position by pessaries, tampons, and knee-chest position; pelvic massage and vaginal douches; proper hygiene, particular attention being paid to the bowels, clothing, and exercise. *Curative treatment:* The choice lies between ventral suspension of the uterus and shortening of the round ligaments.

Ventrosuspension: "An incision is made through the abdominal wall in the median line just above the symphysis pubis and extending upward for a distance of two inches. The index and middle fingers of the left hand are passed into the peritoneal cavity and gently inserted between the uterus and the rectum. The adhesions are then carefully separated and the fundus of the uterus lifted forward into its normal position. The peritoneum at the lower angle of the wound is seized with hemostatic forceps and drawn into the incision and the first suspension suture introduced close to its divided edge on the left side. The index and middle fingers of the left hand are then passed into the abdominal cavity and the uterus securely held while the suture is passed through the fundus. The suture is now introduced into the fundus directly on a line dividing the uterus transversely into two equal halves and buried one-quarter of an inch deep in the uterine tissue with a distance of about half an inch between the points of entrance and exit. The uterus is then released by the fingers of the left hand and the suture passed through the peritoneum opposite to its point of entrance. The second suture is now passed through the peritoneum on the left side one-quarter of an inch above the first suture. It is then passed through the fundus about one-quarter of an inch behind the first suture, and finally through the peritoneum opposite to its point of entrance. It is not necessary to hold the fundus between the fingers while the second suture is introduced, as the uterus can be easily controlled by making traction upon the free ends of the first suture. After both sutures have been introduced their free ends are seized with forceps and placed on each side of the abdominal incision. The through-and-through sutures closing the abdominal incision are introduced and suspension sutures tied. The first three sutures closing the incision at the lower angle of the wound must be introduced so as to pass completely under the peritoneum at its points of attachment with the fundus, otherwise the weight of the uterus will cause stripping and a large dead space will result which will eventually become filled with serum or blood and suppurate. After all of the incision sutures are introduced the suspension sutures are drawn taut so as to take out the slack and bring the fundus of the uterus up against the peritoneum. The sutures are then tied and their free ends cut off close to the knots. The abdomen is closed and the wound dressed in the usual manner. The fascia is first united with a continuous suture of catgut and the wound then closed by tying the through-and-through sutures. The sutures in the lower angle of the wound are tied first, and special care must be taken to remove the slack and bring the peritoneum, at its points of attachment with the fundus, snugly against the abdominal wall." (Ashton's *Gynecology.*)

6. *Treatment of acute pelvic cellulitis:* "The patient is confined to bed, the bowels are kept regular by means of saline purgatives, and warm vaginal douches should be frequently administered by a careful nurse. Glycerin tampons help to relieve the pelvic congestion. When there is much abdominal pain, warm fomentations to the hypogastrium give great relief. When suppuration occurs and the pus can be localized, an incision should be made into it and the abscess drained." (Sutton and Giles's *Diseases of Women.*)

7. *During the menopause:* Menstruation first becomes irregular both in periodicity and quantity, and then ceases; the patient suffers from hot flashes, giddiness, pains in breasts, abdomen or limbs; indigestion, flatulence, constipation, and obesity may be present. The ovaries become smaller and wrinkled, the vagina becomes smaller, the cervix atrophies, the body of the uterus diminishes in size, the pubic hair becomes less, and is shed, the external genitals atrophy.

8 and 9. SPECIFIC VAGINITIS is due to gonorrhea.—*Etiology:* The gonococcus of Neisser. *Symptoms:* Pain and burning in the vulva; pain and burning on micturition; dyspareunia; yellowish or greenish discharge, in which the gonococcus can be found; the vagina is hot, red, swollen, and tender. *Possible results:* Cystitis, urethritis, vulvitis, endometritis, salpingitis, septic peritonitis, sterility, condylomata of vulva, abscess of Bartholin's glands. *Diagnosis* is made from the symptoms, particularly from finding the gonococcus in the discharge. It is so *serious* on account of the possible results enumerated above; it often leads to chronic invalidism, and may be the cause of death.

Treatment: Rest, if possible in bed; freedom from alcoholic or sexual excitement; a mild and unirritating diet; salines and diuretics; plenty of water to drink; a warm sitz bath; douching of vagina with about a gallon of a 1:5000 bichloride solution, or of borax (1 dram to the quart), or of potassium permanganate (1 per cent. solution); the douche is to be taken in the recumbent position.

10. *Salpingitis* is inflammation of the Fallopian tube. *Causes:* Gonorrhea, septic infection, subinvolution, fibroids, uterine displacements, lacerated cervix, taking cold at menstrual periods, and certain diseases such as the eruptive fevers and syphilis or tuberculosis. *Symptoms:* Pain or discomfort, made worse by pressure, examination, defecation; or colicky pains over the tube; dysmenorrhea; increased menstrual flow; tubes are found to be dilated and swollen. *Varieties:* Hematosalpinx, when tubes are distended with blood; Pyosalpinx, when they contain pus; Hydrosalpinx, when they contain serous fluid or exudate. *Diagnosis:* A dragging sensation in the neighborhood of the affected tube; colicky pain, which is increased on exertion or even on standing; abdominal tenderness; menstrual disorders, as amenorrhea, metrorrhagia, dysmenorrhea, menorrhagia; dyspareunia; there may be septic symptoms and peritonitis; sterility generally ensues. On examination there will be found a fullness in Douglas' pouch and one or both lateral fornices; in these latter will be felt either the tubes, distorted and possibly adherent, or a sausage-shaped tumor, which is very painful; the uterus is retroverted or retroflexed, and may be bound down by adhesion; there may be an intermittent expulsion of pus accompanied and preceded by a burning pelvic pain. *Treatment:* Rest in bed, hot vaginal douches, saline purgatives, liquid diet, morphine (if necessary) for

pain, removal of pathological conditions and complications; radical operation (salpingectomy, or salpingo-oophorectomy) may be necessary.

SURGERY.

1. *Corneal ulcer* is detected by oblique illumination, the ophthalmoscope, or convex lens, and by dropping fluorescine upon the cornea, the denuded area being colored green. Pain, photophobia, lacrimation, swelling of the lids and conjunctiva, and destruction of tissue are symptoms. Corneal opacities, staphyloma, perforation, adherent leukoma, atrophy of the eyeball, and prolapse of the lens and vitreous may result. The *treatment* consists in putting the eye at rest, instilling atropine, and the application of a bandage. Leeches to the temple will relieve the pain. Hot compresses have the same effect. The eye should be douched with sublimate solution, 1:5000, and iodoform dusted upon the cornea. Stronger sublimate solution, boroglycerid 50 per cent., and formalin 10 per cent. are sometimes necessary. Cauterization is occasionally indicated. If perforation seems probable, it should be hastened by a puncture.—(*Cyclopedia of Medicine and Surgery.*)

2. ABSCESS OF THE BRAIN.—*Causes:* "Pyogenic infection is the cause in all cases, and the commonest method is by spreading from chronic otorrhea. Other cases are traumatic in origin, as in septic compound fractures and penetrating wounds, the frontal and parietal lobes being then chiefly affected. The commonest seat of abscess in the brain, due to middle-ear disease, is the cerebellum. The next most common seat is the temporo-sphenoidal lobe. The suppuration may extend directly through the tegmen tympani, the membranes and brain becoming first adherent to it; but usually there is a healthy area of brain intervening, so that the extension of infection has been along the course of vessels and lymphatic sheaths running between the brain and middle ear. Similar abscesses rarely follow suppuration in the frontal, sphenoidal, and ethmoidal sinuses, and thrombosis of the cavernous sinus. Pyemic and chronic tuberculous abscesses also may occur. An abscess in the brain is usually chronic, but terminates in compression, either from the onset of spreading edema or rupture into one of the lateral ventricles.

The *symptoms* in traumatic cases are acute, and, as there is usually diffuse meningitis, there is intense pain, fever, and rigors, coma quickly supervening. In the more common chronic cases the symptoms are often vague in the early stages, but when well marked consist in signs of intracranial pressure. 1. The headache and tenderness are severe and localized to the site of the abscess. 2. The temperature is subnormal, unless there is associated meningitis. 3. The pulse is markedly slowed, even down to 30 or 40. 4. The patient is quite intelligent, but cerebration is very slow; vomiting and optic neuritis are usually present. 5. Motor symptoms may occur if the abscess is in the anterior part of the temporo-sphenoidal lobe, either irritative or paralytic. If the cerebellum is affected, there is giddiness both while walking and lying down, together with weakness of the hand-grip and increase in the knee-jerk on the side affected. Lateral nystagmus often occurs.

Treatment: The abscess must be opened as soon as possible. Unfortunately, many cases are only diagnosable when it is too late for evacuation to produce a cure. As cerebellar abscess is more common, it is as well to explore the cerebellum first, unless focal symptoms point to the temporo-sphenoidal lobe as the site. A flap is turned down and a piece of bone removed with a trephine. The dura is then incised and the abscess punctured with a trocar and cannula or sinus forceps. These should be passed in various directions till the pus is found, and then the opening must be enlarged, the pus gently washed out, and a drain left in for several days.

For a temporo-sphenoidal abscess the trephine opening should be made ¾ in. above the posterior root of the zygoma, and directly above the posterior border of the bony meatus; for a cerebellar abscess, 1½ in. behind the center of the external auditory meatus and 1 in. below Reid's base line. In most cases the mastoid antrum should be first explored; by removing the bone behind it the lateral sinus can be exposed, and by working above or below it the cerebrum and cerebellum can be explored.—(*Aids to Surgery.*)

3. "*Abscess or empyema of the antrum of Highmore* is a collection of pus within the maxillary antrum. It results from inflammation of the jaws, the teeth, or the mucous membrane of the nose. It causes pain, edematous swelling of the overlying soft parts, and crepitation on pressure upon the superior maxillary bone. Pus may escape from the nostril of the diseased side when the head is bent in the direction of the healthy side. A rhinoscopic examination discloses the fluid passing into the nares. The antrum on the side of the abscess cannot be transilluminated by an electric light in the mouth. The constitutional symptoms of suppuration usually arise. *Treatment:* Bore a gimlet-hole through the superior maxillary bone, above the canine tooth, or perforate the bone by means of a trocar. Irrigate daily with boiled water or normal salt solution. Keep the opening from contracting by inserting a small tent of iodoform gauze. In persistent cases it may be necessary to draw a tooth, break through the socket of the first or second bicuspid into the antrum, and insert a silver or hard-rubber tube, and also to perforate the antrum from the inferior meatus and keep the opening patent. In very persistent cases osteoplastic resection of a portion of the upper jaw will be demanded." (DaCosta's *Surgery.*)

4. *The symptoms of hyperthyroidism* are thus given by Schaeffer: Lowered blood pressure; rapid pulse, often with some irregularity; nervous excitability; flushing of the skin, with feeling of heat; increase of perspiration; and increase of nitrogen metabolism. If long continued the fat of the body is diminished and glycosuria may be caused. There is considerable wasting, although the appetite is increased. There are often digestive disturbances. In extreme cases there may be exophthalmos and other effects referable to cervical sympathetic excitation, such as dilatation of the pupils; psychical excitement; sleeplessness; tremors of the limbs; in short, most of the symptoms of exophthalmic goitre.

Surgical treatment: The whole gland must not be removed, or myxedema may result; and the parathyroids must not be removed, or the patient may develop tetany. Ligation of one or more of the thyroid vessels may be done, or one-half of the gland may be removed. Local anesthesia is safer than general anesthesia in these cases.

5. *Treatment of gunshot wounds of the chest:* "After the application of a clean dressing the patient should be put to bed with shoulders elevated to insure comfort. Transport should be delayed until danger of complications has passed or until the wounds have healed. (Failure to observe this may result in hemothorax and empyema.) Chest cases should be treated in the first aid zone whenever practicable. The majority of cases of hemothorax are slight and require no treatment other than rest in bed. When the amount of blood embarrasses respiration aspiration is in order. When practicable this should be delayed to a time when injured vessels have had sufficient time to heal lest coagula are disturbed with the recurrence of hemorrhage. The source of hemorrhage is generally from the intercostals or mammary arteries. When it is not practicable to ligate the bleeding vessels, pressure by Desault's method should be practised. This is accomplished by pressing the center of a square piece of gauze in the wound with the finger and subsequently packing the pocket thus made with loose gauze. The corners of the gauze originally pressed in by the finger are pulled upon to make pressure on the internal surface of the wound next to the sternum or ribs. When large quantities of clotted blood fail to be absorbed, or infection sets in, free incision and resection of part of one or more ribs should be practised, followed by thorough irrigation." (*Reference Handbook of Medical Sciences.*)

6. The *causes of acidosis after surgical anesthesia* are thus given by Grove: In *fat children* it may arise spontaneously without other disease, and cause recurrent attacks of vomiting. *Sepsis* is only a contributing factor. *Trauma* or severe operation may produce acidosis. *Chloroform* acts as a protoplasmic poison and causes fatty degeneration of liver and kidney cells. *Ether* may act in the same way but to a less extent. The majority of cases have occurred when chloroform has been given to fat children or diabetics, with pre-existing acidemia, for a serious operation. *Treatment*

consists in copious infusions of solution of bicarbonate of sodium (one dram to the pint) both intravenous and rectal.

7. The laboratory tests include examination of the urine and the blood. *Preparation for operation:* "Whenever possible the patient should be under observation for at least two days before operation, in order that the patient himself, as well as the disease, may be carefully studied. The history is taken, and a thorough examination, especially of the heart, lungs, urine, and blood is made. The diet should be free of vegetables and consist principally of albumins, in order to leave little residue in the intestines, which are cleared by laxatives, usually calomel, ½ grain every hour for eight doses, followed by magnesium sulphate, half ounce. This prevents autointoxication, and in abdominal work renders the intestines docile, so that they may be kept from the operative field by gauze packing. Before operations on the mouth, esophagus, and gastrointestinal tract the number of bacteria in the alimentary canal may, aside from purgation, be diminished by removing carious teeth and tartar, frequently rinsing the mouth with an antiseptic wash, and sterilizing all food. Hexamethylenamine, because of its antiseptic effect upon the bile, the urine, and the cerebrospinal fluid, may be administered previous to, as well as after, operations involving the biliary tract, the urinary apparatus, and the central nervous system. The patient is given a daily soap and water bath, and should, in order to prevent 'colds,' wear an undershirt in bed, if so accustomed.

"The day before operation the part to be operated upon is shaved, and then, after disinfection of the hands, it is surrounded with sterile towels and thoroughly scrubbed with soap and water, using a sterile brush with soft bristles, or a piece of gauze if the skin is tender. Special attention is given to folds and creases in the skin and to such places as the umbilicus. The disinfection should extend around to the spine, up to the breasts, and down to the pubes, including the upper part of the thighs. After scrubbing with soap and water, the skin is rubbed with alcohol (70 per cent.), in order to dissolve the sebaceous matter and fat in the mouths of the glands, and thus clear the way for the bichloride of mercury solution, 1 to 1000, with which the part is next scrubbed. Gauze soaked in bichloride of mercury (1 to 2000) and covered with waxed paper, or, better, a dry sterile dressing, is applied to the disinfected region until the time of operation, when the whole procedure is repeated. A nervous sedative may be administered the night before the operation, if the patient is unable to sleep. No food should be given for at least six hours before operation, in order that the stomach may be empty and that vomiting may not occur. Several hours before operation the rectum should again be cleansed by a soap and water enema, one pint, so that any stimulating or nutritious fluids may be absorbed in case their injection becomes necessary. Immediately before operation the patient should pass urine or be catheterized, so that voiding will not occur on the table, so that there will be no danger of injury to the bladder, and so that the surgeon will know the exact quantity of urine secreted subsequent to the operation." (Stewart's *Surgery.*)

8. *Acute intussusception* "is most common in children. It begins suddenly with severe abdominal pain and vomiting. Blood-stained mucus is passed, perhaps with tenesmus. Collapse soon comes on, and may be fatal in twenty-four hours; otherwise death occurs in a few days from peritonitis. In most cases a 'sausage-shaped' tumor can be felt, usually along the course of the colon, but lower down, or just above the pubis. The right iliac fossa feels empty. A natural cure may follow, but rarely, from sloughing of the intussusceptum, while the peritoneal cavity is protected by adhesions uniting the entering and ensheathing layers.

"*Treatment:* The reduction of the intussusception at the earliest possible moment is the only treatment admissible, and this can only be done with certainty by operation. The abdomen should be opened over the tumor if it can be felt; if not, in the mid-line below the umbilicus. The intussusception is then reduced by squeezing out the entering portion, beginning at the lowest part. The intestine should never be pulled out, for fear of tearing it. If there is any difficulty, the wound must be enlarged and the lump brought out. If, owing to adhesions, reduction cannot be done, the intussuscepted portion must be excised through an incision in the ensheathing layer, but the outlook is bad in these cases. If the bowel is gangrenous, the condition is so bad that nothing more can be done than to bring out the coil and establish an artificial anus. If, owing to any reason, an operation is not possible, non-operative procedures must be tried. These consist of attempting to reduce the invagination by inflation with air, or better still, by fluid. A catheter is passed into the rectum, and fluid poured in from a funnel raised not more than 2 feet. A hand is placed over the tumor to feel when the lump disappears. The objections to this are that after twelve hours reduction cannot be obtained by this method; that valuable time is wasted if it fails; that you cannot tell if the last inch has been reduced (and if it has not, recurrence is certain); that it is no use in the enteric or ileo-colic forms; and that the bowel may be ruptured." (*Aids to Surgery.*)

9. *Treatment of osteomyelitis of the tibia* is immediate incision down through the periosteum; the surface of the bone must be opened with gouge or chisel, pus evacuated, and drainage instituted; irrigation with hot bichloride solution and packing with gauze. The medulla of the bone must be freely exposed, and any suppurating material removed. Constitutional treatment and rest are, of course, indicated.

10. "In the treatment of compound fractures the main object is to render the wound antiseptic and to give efficient exit to the discharges. For this purpose the patient should in all cases be anesthetized, the limb shaved, and thoroughly purified, and the wound enlarged and thoroughly washed out with some reliable antiseptic. It may be advisable to excise torn and dirty fragments of skin, muscle, and tendon, especially when dirt has been ground into them. Loose fragments of bone are removed and portions denuded of their periosteum may be taken away lest necrosis should ensue; where fragments retain any considerable connection with the soft parts they may be left without fear. When a sharp end of one of the fragments is protruding through a small opening in the skin it is first purified thoroughly before attempting its reduction and then replaced after enlarging the wound in the skin, or a portion sawn off. Hemorrhage is dealt with in the usual way, and the fragments are placed as nearly as possible in their normal position. If the fragments can be brought accurately into position it is well to fix them by some mechanical appliance; but where the ends of the bone are much comminuted the small portions must be arranged in position as well as possible, and no attempt made to wire them. A good-sized drainage tube is inserted, and, if need be, counter-openings are made; the external wound is closed or not, according to circumstances, and dressed, and suitable splints are then applied. Under such a régime the majority of cases do well. Immovable apparatus may be used after a time, windows being left in the plaster casing to allow wounds to be dressed." (Rose and Carless' *Manual of Surgery.*)

In case of Pott's fracture the fracture should be reduced by relaxing the calf muscles and applying traction to the foot. The limb must then be fixed on the back splint, with side splints in addition. The foot must be at right angles to the leg, the bony points in line, and the posterior displacement corrected. The surest way of maintaining the foot in good position is to at once apply plaster of paris. Other splints used are Dupuytren's and Syme's horseshoe splint.

HYGIENE.

1. The danger in surface waters and dug wells lies in the fact that filth, sewage, and, indeed, anything *may be* conducted into these waters. Hence, the possibility of disease being caused by drinking this water. The wells and springs should be at a distance from dwelling houses, especially from outhouses, privies, etc.; they should be well protected and covered, so that no extraneous matter can enter them. All shallow wells should be protected with good coping stones and good masonry for several feet below the surface.

2. Extra crowding must be avoided; animals should not be kept indoors; the maximum of sunlight and fresh air should be obtained; the plumbing and heating ar-

rangements should be in as good repair as possible; every case of communicable disease should be promptly reported and removed to hospital; the place should be kept as clean as possible; flies, rats and mice, etc., should be excluded; garbage and refuse must be removed promptly.

3. *Practical steps to prevent the spread of venereal diseases in a community:* (1) The scientific and practical control of prostitution (this is always opposed); (2) the education of the public on the dangers of venereal diseases (this is generally opposed); adequate instruction in hygiene in the public schools.

4. *Some of the ill-effects of school life on the health of children:* Dyspepsia, headaches, nervous troubles, chorea, epilepsy, neurasthenia, back aches, defective eyesight, spinal and other physical deformities, skin diseases, infectious diseases.

5. *The duties of a medical supervisor for a school* include regular and thorough inspection of the school premises and buildings; regular and efficient inspection of the pupils by physicians; prompt exclusion and isolation of any one suffering from a contagious disease, or coming from a house where such disease is; compulsory notification of all infectious and contagious diseases; individual towels, drinking vessels, and other implements; children who have had a contagious or infectious disease or who have come from a house where such disease prevailed should not be readmitted to school until sufficient time has elapsed since the occurrence of the last case to insure safety.

6. A *first-class eating apartment* should be clean, light, airy, well ventilated and (in winter) properly but not excessively heated; there should be no back yards with exposed garbage, no flies; plenty of water, and screens; the employees should be clean and healthy; there should be no cooking of food in the eating rooms; there must be adequate room for food storage, also ice boxes or refrigerators in clean condition; all the furnishings and table equipment must be clean.

7. *Ice* may be as impure as the water from which it is made; hence it may convey most of the diseases which can be conveyed by water: typhoid, cholera, colon bacillus infection, dysentery, etc.

8. The mosquito which transmits malaria is the *Anopheles.* Its wings are usually spotted; in the resting posture, the axis of the head, proboscis and body are in the same straight line; its body is of a dark gray or brown color; the female alone bites and transmits the *Plasmodium malariæ;* the larvæ float on the surface of water.

9. *Autogenous vaccines* should be used whenever possible. Being prepared from the patients' own bacteria they are much more likely to be curative than stock vaccines. In some diseases, such as pneumonia, vaccines made from one strain will not protect against another strain.

10. *Sewer gas* is a mixture of a number of gases, such as carbon dioxide, ammonia, hydrogen sulphide, and certain organic matters the result of animal and vegetable decomposition. When large quantities are inhaled there may result vomiting, headache, prostration, purging, loss of appetite, anemia, and general impairment of health.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE SURGERY OF ORAL DISEASES AND MALFORMATIONS. Their Diagnosis and Treatment. By GEORGE VAN INGEN BROWN, D.D.S., M.D., C.M., F.A.C.S. Third Edition. 734 pages. Illustrated. Price, $7.00. Published by Lea & Febiger, Philadelphia and New York.

Miscellany.

The Practice of Medicine in Cuba.—Dr. Lainé of Havana, who moved from Philadelphia to Cuba in 1898, recently gave an interesting account of his twenty years' experience on the island in the *Revista Medica Cubana.* Upon his arrival he found the Cubans practising in accordance with European traditions, especially favoring the French school. At this period, it will be recalled, the island was just undergoing its first experience under a free government. After the revolution the hospitals and other medical charities were left in a deplorable condition and the author was requested by the Military Commission on Evacuation to examine these institutions and report to them his findings. The author's first patient, seen in consultation with a Cuban colleague, was an American ill with typhoid fever in a large Havana hotel. When he returned the following day he found that the patient had been removed to the colleague's private clinic. Soon afterwards he saw in consultation a Cuban patient and was afterwards requested by the family to take charge of the case. The request he refused as unprofessional. The fee for a consultation at that time was but $10 instead of the $25 often demanded in the United States by exclusively consulting practitioners.

Of interest to the American medical visitor were the various institutions for the sick in which many thousands of individuals received treatment annually. These institutions were known in Spanish as quintas and at first sight seemed to represent a worthy charity, but they tended to pauperize the beneficiaries, while at the same time they influenced unfavorably the practice of medicine. The amount of good done was very small; but few physicians were employed and the emoluments of the latter were not large. Each medical attendant was obliged to examine and treat 70 or 80 patients in a few hours. A quinta physician once informed the author that in one day's service he had prescribed a laxative for 60 patients of the 80 who came to consult him. Diagnosis was, of course, out of the question in such cases.

The Cuban has the genuine American fondness for proprietary medicines. Salts and calomel are used in medicinal heroic dosage. The natives are great meat eaters and cookery is far from scientific. Ailments ascribed to excess protein consumption, as uric acid morbidity and arteriosclerosis, are common. The Cuban fears the night air and sleeps with closed windows. This fear was once well grounded, for the precaution doubtless was a wise one when insect-borne diseases prevailed. Nocturnal air is also relatively cold and very damp. Acute lobar pneumonia and acute articular rheumatism are both rare in Cuba. Scarlet fever, whooping cough, and influenza run a mild course. Dengue affects the eyeball in a specific way, causing both pain and tenderness to pressure. In conclusion the author cites the extreme natural conservatism of all Latin-Americans, and says that, bearing this in mind one may say that the medical profession in Cuba has accomplished a great deal in twenty years and has absorbed much good from the United States.

A CASE OF PERFORATION OF THE DUODENUM TREATED SUCCESSFULLY BY DUODENAL (JEJUNAL) ALIMENTATION.

BY MAX EINHORN, M.D.,

NEW YORK,

PROFESSOR OF MEDICINE AT THE NEW YORK POSTGRADUATE MEDICAL SCHOOL; VISITING PHYSICIAN TO THE LENOX HILL HOSPITAL.

(From the Lenox Hill Hospital, New York.)

PERFORATION of the duodenum may be advantageously divided into two groups: (1) Internal (intraabdominal). The symptoms are all internal, the perforation is usually the result of an ulcer which has ruptured. The whole catastrophe plays within the abdomen. The diagnosis is made with some difficulty, and also uncertainty. The treatment is surgical, and the sooner the condition is recognized and operated upon the better are the chances of recovery. (2) External (extraabdominal). Some of the symptoms involve the external surface of the body. The perforation here is generally due to some recent cause, trauma and the like, and occurs after operations, principally on the gall-bladder and its ducts. The rupture of the duodenum leads to a fistulous opening, which permits an outpouring of duodenal contents (food particles, pancreatic juice, bile) outside of the abdomen through the laparotomy wound. The powerful pancreatic juice irritates

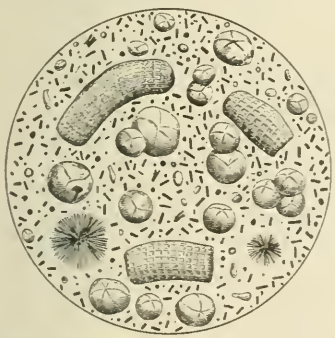

FIG. 1.—Miscroscopic picture of the contents from the fistula of Mrs. A. L. M. on March 13, 1918: Starch cells; muscle fibers; tyrosin crystals; fat globules; bacilli and cocci.

the wound surface and the skin, which undergo partial digestion. The surface surrounding the fistula is greatly inflamed and painful. The diagnosis is easily made with exactness (finding of food and pancreatic juice in the secretion of the wound). The treatment in this group is ordinarily more difficult, and the prognosis very grave indeed.

The case to be reported belongs to the second group. It will therefore be of interest first to discuss this variety more fully, detailing the prognosis,

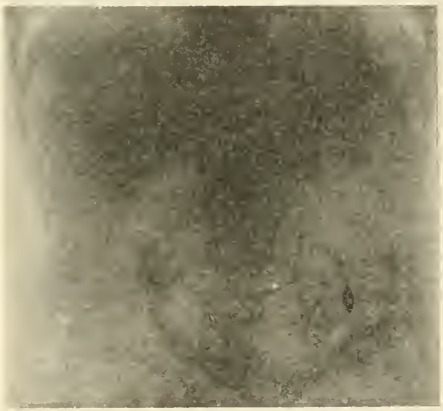

FIG. 2.—*X*-ray of Mrs. A. L. M., after filling the duodenal tube with a bismuth mixture. The tube is seen running along the stomach, duodenum and jejunum. April 26, 1918.

symptomatology and treatment. Then the case will be described and the new regime of treatment.

Most writers consider the prognosis of a perforation of the duodenum as very grave. Thus Pannett[1] says: "Recovery from a duodenal fistula, even with adequate surgical treatment, is a rarity. Only three cases are to be found in the writings of the last ten years."

Pannett operated upon his patient. The duodenal-jejunal flexure was identified, and a loop about eight inches from this drawn out of the wound. The afferent and efferent limbs at the base of this loop were made to communicate by a lateral anastomosis. A rubber catheter was sutured into the efferent limb of the loop according to the technique of Witzel for gastrostomy. The bend of the loop was then sutured to the parietal peritoneum and the wound was closed. Feeding through the jejunostomy opening was regularly performed, and food was also given by mouth. In ten days the fistula closed. Now the jejunostomy tube was withdrawn. No leakage took place. The patient made a rapid recovery.

Berg[2] thus expresses himself regarding the prognosis of duodenal fistula: "A duodenal fistula, unless it is of pinhole size, usually occasions a very rapid death from starvation."

In this paper Berg recommends a gastrojejunostomy and pyloric occlusion for the cure of duodenal fistula. He has performed this operation on two patients and had partial success in one. Berg also considers the point whether in cases of ruptured duodenum that may be followed by a fistulous opening it is advisable to resort to a primary gastrojejunostomy and pyloric occlusion in addition to repairing the opening in the duodenum, or to content ourselves at the first operation with direct repair of the perforated viscus. Berg answers this question with the following words: "If the peritoneal surfaces surrounding the perforated part are normal in character, and are not brittle or friable, or fixed in inflammatory or neoplastic exudate, we have every reason to expect a successful issue to our efforts at repair by suture; but if this healthy yielding condition of the surrounding peritoneal surfaces does not exist, it is not likely that the healing by suture will occur, and in such cases it would be wiser, if the patient's condition permits of it, to at once proceed to gastrojejunostomy and pyloric occlusion."

Palmer,[3] in a recent excellent paper on duodenal fistulas says: "Experience gained during apprenticeship from association and hearsay and in two personal cases forces me to conclude that fistulas of the duodenum following operative procedures are neither the rare nor the simple benign affairs the silence of the professional pen might lead one to conclude. Reference to this subject has almost invariably a pessimistic tone, and but little encouragement is given. The symptoms of duodenal fistulas are succinctly given by Palmer as follows:

1. Inanition is such as will occur following a fistula in no other part of the intestinal tract, and is comparable in effect to a break in a mill race above the water wheel—no power is obtained.

2. Dehydration rapidly follows unless energetically combatted by rectal or subcutaneous injections. This dehydration follows the loss of a large output of fluid in the form of bile (1 liter), pancreatic fluid (0.5 liter), etc., and also the interference with the fluid absorption.

3. A marked specific toxic action may follow the systemic absorption of the normal or changed secretions from the uncovered fistulous tract.

4. The digestive action of the normal secretions has full sway on the duodenal fistula and the tract leading to the surface, to such an extent that the hole shows a progressing enlargement, in contradistinction to the behavior of most other intestinal fistulas. Digestion of the skin of the abdomen and back is so rapid and unrelenting as to make the life of the patient a hardship to himself because of discomfort and pain, and to the nursing force because of the frequency of the needed dressings.

5. The secretions to be controlled are so varied as to render the problem more difficult than appears at first sight. These are the secretions of the stomach, the liver, the pancreas, and the duodenum itself.

6. Bleeding from the raw surface of the tract may assume alarming proportions.

7. Fat necrosis is sometimes observed in these cases.

8. Extension of the peritoneal inflammation may occur, owing to the digestion of adhesions.

9. The amount of discharge is out of all proportion to the size of the aperture; this may be due to the sphincteric action of the circular muscle fibers at this location.

Palmer had two cases of duodenal fistula which he successfully treated medically.

The expectant treatment, according to Palmer, has the following objects in view: (1) Protection of the skin and the tract itself against the digestive action of the secretions; (2) introduction of fluids and nourishment in quantities sufficient to maintain not only life but also the reparative power of the tissue; (3) reduction in the amount of gastric and intestinal secretions; (4) neutralization and dilution of these secretions.

1. The use of a low-melting-point paraffin applied hot to the dry skin is good. . . . For the tract itself the injection of liquid petrolatum and zinc oxide ointment to the bottom of the tract is not only painless but is apparently of benefit; and liquid petrolatum, because an inert mineral oil, should be given by mouth in large doses, so that it may in part coat the fistulous tract from within out.

Fig. 3.—Same as Fig. 2, after the ingestion of barium and sago into the stomach. The tube is discernible as above. The stomach is visible as a mottled area above the capsule end of the tube. April 26, 1918.

2. Glucose (10 per cent.) by rectum, with plenty of sodium bicarbonate. Later, when food is given by mouth it must be such as will produce the least secretory stimulation.

3. Milk, fats, oils are then permitted, while beef extracts are forbidden. Alkalies, atropine, and epinephrin are recommendable.

In the foregoing the expectant medical treatment, as outlined by Palmer, and the surgical treatment as suggested by Berg and Pannet, have been described. In short, the principle consists in keeping the stomach and duodenum as empty as possible, while the organism should receive as much nutritive material and fluids as conditions permit. In the medical plan of treatment the main avenue of nutrition and fluid instillation is the rectum. In the surgical regime the jejunum is utilized for nutrition, either by a jejunostomy (Pannet) or by a gastrojejunostomy and pyloric occlusion (Berg). The pyloric occlusion serves to divert the chyme from entering the duodenum and irritating the fistulous opening.

The duodenal tube, when made to reach the

jejunum can accomplish all that the suggested operations do without the necessity of cutting. It furnishes at once a perfect canal for the introduction of nutritive material and fluids into the jejunum and it also prevents the entrance of chyme into the affected duodenum. The stomach being kept without food, there is usually no gastric juice. If there should be gastric secretion anyway, additional medication with atropine will accomplish its cessation.

The plan of treatment will, therefore, consist in introducing the duodenal tube (a long one) into the jejunum, and as soon as the tube has reached this place to commence feeding according to the rules of duodenal alimentation.

Duodenal alimentation was first used in a perforated gastric ulcer by Dr. N. de Rosas,[1] with perfect recovery.

A similar plan of treatment was successfully carried out by Dr. Willy Meyer and myself in the following case of perforation of the duodenum. We are both confident that this measure saved the life of the patient, for she was not in condition to have stood the risks of any additional operation.

Case.—On July 1, 1917, Mrs. A. L. M., about 40 years old, had a severe attack of pain in the upper abdomen, lasting ten days, and requiring codeine to allay it. The pain radiated toward the back and was quite pronounced below the right shoulder blade. There was tenderness over the region of the gallbladder.

On September 6, 1917, there occurred another severe attack of abdominal pain, lasting twenty-four hours, with remission for thirty-six hours, and reappearance for twelve hours. Patient felt chilly during the attack.

On September 21, 1917, patient complained of some discomfort in the epigastric region. There was tenderness on pressure in the epigastrium, principally under the right costal margin.

From October 11 to 15 I had the patient under observation. The gastric contents showed HCl + acidity = 40; the string test was negative; the examination of the duodenal contents in the fasting condition showed greenish brown, turbid; Alk = 20; A = 8; S = 2; T = 3. The digestive test capsule passed in forty-eight hours, all the test substances having disappeared. The *x*-ray revealed a somewhat enlarged gall-bladder, with probable stones. The blood showed no leucocytosis. The diagnosis was cholecystitis with probable gallstones. While in the hospital the patient had another attack of pains and became slightly jaundiced.

The patient was operated upon on October 27, 1917, by Dr. Willy Meyer. The gall-bladder was found to be distended, dark (not bluish), with greatly enlarged blood vessels. No stones in bladder or ducts. Diagnosis: "Cholecystitis without stones." Cholecystectomy was performed, the cystic duct tied with chromicized catgut; the gall-bladder, when incised after removal, showed velvet-like mucosa and was dark brown. The bile, aspirated before incision, was dark brown like Kulmbacher beer. Twelve hours after the operation bile appeared in the dressing. A few days later jaundice developed. The wound drained plenty of bile and patient gradually improved. She left the hospital November 25, 1917.

The loss of bile from the wound continued to be excessive and jaundice appeared as soon as the flow lessened. Patient lost considerably in weight. At times, when the bile did not drain off well from the wound, she suffered from colicky pains. This condition continued from November, 1917, until February 18, 1918, in spite of all attempts to bring the biliary fistula to a close. Then, with no prospect of improvement, it was decided to have the patient undergo a secondary operation, with the object of finding and removing, if possible, the suspected stone in the common duct.

On February 21, 1918, Dr. Willy Meyer undertook this operation. After a most thorough exposure and painstaking search the task had to be given up, as the patient's condition became so alarming that any further handling might have had a fatal issue. It had been intended to open the duodenum and probe the bile ducts through the papilla of Vater as a last resort for bringing relief. The wound was closed by sutures and drained. On February 24 and 25 there was continuous profuse parenchymatous bleeding from the wound, necessitating a blood transfusion, which was done on February 26 with much success.

After gradual improvement, patient felt much worse on March 10, was restless, and complained of an intense itching and burning in the wound and on the surface of the skin surrounding it. The skin looked dark red and somewhat eroded. The contents of the fistulous opening had a yellow brownish turbid look. Upon examining the contents we found pancreatic juice and bile in it, and also food particles; the specimen obtained from the wound was turbid, dark yellow, with a tinge of green, and sediment; Alk = 55; A = 3; S = 1.5; T = 11; microscopically: muscle fibers, starch cells, and tyrosin crystals. (See Fig. 1.)

A perforation of the duodenum had, therefore, taken place, making the patient's condition very grave. On March 12 I introduced the duodenal tube, which did not enter the duodenum until the morning of the 14th. We had selected a specially long tube and we made it pass beyond the duodenum into the jejunum (95 cm. from the lips). Patient was first fed in the usual way through the tube by the syringe method, giving her the standard milk, egg, and lactose mixture. She, however, complained of so much nausea, fullness, and distress that Dr. Meyer and myself decided to give her milk and lactose through the duodenal tube by the drip method. She took three quarts of milk and a considerable quantity of lactose and also saline daily, which she stood very well. On April 2 the old tube was removed and a new one introduced. Patient during this time had picked up considerably in strength and probably also in weight. The skin near the wound looked normal and there was not much flow from the wound noticeable.

On April 19 the fluid collected through the wound from the fistula showed: yellow clear; A = 0; S = 0; T = 0; no food remnants. This indicated that the hole in the duodenum must have healed. On April 26 an *x*-ray was taken showing the tube in the jejunum (see Figs. 2 and 3). On April 29 the tube was removed. On April 26 the bile stopped flowing from the wound and the patient had a chill with a temperature of 104°. When the bile began to flow the temperature went down to normal. This occurred again on May 1 and 2, when the temperature rose to 106° and jaundice increased. On May 10 the duodenal tube was reintroduced with the object of flushing the system and in this way allaying the septic state. The bile began to flow profusely on May 15, and the patient began to improve. In the bile from the fistula there were never any more food particles found nor pancreatic juice. On June 6 the duodenal tube was definitely removed. In order to build the patient up and save her from the great loss of bile through the fistula, the bile was collected in a bottle and twice daily poured into the stomach by means of a catheter.

Patient has since picked up considerably in weight and is up and about. There is no jaundice. Still there exists some leakage from the fistula, which is kept open by means of a small drainage tube. The greater amount of bile flows into the duodenum; stools are well colored. The patient needs further treatment and probably another operation.

Remarks.—In our patient, perforation of the duodenum had taken place some time after a laparotomy. Patient was then so weak that operative intervention could not have been thought of. Nor would any expectant plan of treatment have been of any material assistance. The rectum would not have sufficed to keep the patient alive for the long period required for the healing of the fistula. Jejunal alimentation at once removed all the obstacles and smoothed the way toward recovery.

There seems to be no doubt that the jejunal ali-

mentation is the ideal plan of treatment for perforation of the duodenum whenever the fistulous opening leads to an external wound (second group of duodenal perforation). In the first group of perforation (usually duodenal ulcer) an operation is always demanded, and suture of the duodenum after infolding is frequently done. If the tissue is brittle, and there is danger of bursting, Berg recommends, as mentioned above, an additional operation of gastrojejunostomy and pyloric occlusion. I would venture to suggest, instead of adding this operation to use jejunal alimentation right after the laparotomy. This will surely do as much good as the operation of gastrojejunostomy. It has the great advantage of not being connected with any risks and of establishing adequate nutrition right from the start. Another advantage is that by this régime the physiological relations of the viscera remain undisturbed, while a gastrojejunostomy, especially with pyloric occlusion, creates new conditions to which the organism must gradually adapt itself, sometimes with difficulty.

This suggestion does not apply to operations which produce a considerable narrowing of the lumen of the duodenum; here a gastrojejunostomy with pyloric occlusion is a necessity which cannot be obviated.

A CASE OF LABYRINTHAL MENINGITIS,

WITH SUGGESTIONS FOR A NEW LABYRINTH OPERATION.*

By ALFRED KAHN, M.D.,

NEW YORK.

On or about the 7th of April, 1917, Mr. W. R., age thirty, called on me with the history of a discharging ear over a period of years. He stated that this foul discharge, together with headache and at times dizziness, was so unpleasant to him that life had become unbearable, and that on several occasions he had very strongly contemplated committing suicide. The patient had already undergone a radical mastoid operation in Texas the year before, but, if anything, his condition had been worse since the operation.

His physical examination showed a large perforation in the upper posterior quadrant of the drum, from which exuded a foul discharge. The posterior bony canal wall was partially down, and the canal showed evidence of an incomplete radical operation. At the time of this examination, I could not understand why it was that the operator had not finished the radical operation, and it was only at the time when I operated that I discovered a far forward sinus, which had been exposed at the time of the first operation. The operator at that time seems to have been inexperienced and to have hesitated going further, after having exposed this far forward sinus. The patient was not totally deaf in the diseased ear. A radical mastoid was recommended and the patient was admitted to the New York Eye and Ear Infirmary on April 9. At the time of this radical operation, much to my surprise, the necrosed area seemed to be along the floor of the middle ear and to involve the internal wall of the middle ear, especially in the region of the round window. A fistula could not be demonstrated. In my endeavor to remove all necrosis, I fear that at this point in the operation, as I now look back at it, I must have injured the internal wall of the middle ear in the region of the round window. I especially mention this on account of the relation it had with the subsequent symptoms and final outcome of this case. The patient progressed satisfactorily until, on April 11, two days after the operation, he complained of being dizzy and showed a nystagmus towards the healthy ear. The patient complained of dizziness for three or four days, until on April 14, six days after the operation, his temperature rose to 103.5°. From April 9 to April 14 his temperature fluctuated between normal and 100.5°. On April 15, the seventh day after the operation, his temperature rose to 106°. Nystagmus stopped; the patient was totally deaf in the diseased ear. I mention the fact that the patient was totally deaf and his nystagmus halted, as a demonstration that we were here dealing with a dead labyrinth, and because of the fact that according to the Vienna school, the fact of a dead labyrinth occurring in the course of labyrinth disease, associated with meningitis, is a prima facie ground for doing the labyrinth operation. The patient, at this stage, April 15, became unconscious and presented very marked symptoms of meningitis. He had a stiff neck and showed Koenig's sign. He also had a high spinal fluid cell count. This is the case mentioned by Dr. Perkins at a recent session of the Academy of Medicine in his paper on the peculiarities of the spinal fluid in cases of this type. He stated at that time, and has since stated to me personally, that notwithstanding the fact that my patient recovered, having the symptoms of a true case of meningitis following a labyrinthitis, with total destruction of the labyrinth, this labyrinthitis following the radical mastoid operation, I should have done the labyrinth operation. He could not account for this patient's recovery. After April 15 the patient's temperature gradually dropped. He regained consciousness, and except for the fact of facial paralysis, which followed the operation and which is now almost entirely cleared, the patient made an uneventful recovery and was discharged from the hospital April 30. His wound was dressed by me for several weeks after his discharge, and he now has a perfectly dry cavity and is in excellent shape. I have asked the patient to appear here to-night for your inspection.

I have given this case considerable thought, and I attribute his recovery to the fact that the diseased area involved the inner wall of the middle ear, that this wall was soft and necrotic, and that it was further accidentally injured at the time of the radical operation in my anxious endeavor to remove all necrosed bone; that it was through this passage, by way of the internal auditory meatus that the labyrinth was destroyed and that meningitis took place. This wall afterwards broke down (at my subsequent dressings there was a discharge of spinal fluid) and I was able to pass quite a large-sized probe down to the internal auditory meatus. I kept the cavity firmly packed up to almost the end of the last dressing. It is for this reason, if you will examine the patient, that the radical cavity granulated almost up to the surface, and that the radical cavity itself became entirely obliterated. With the experience of this case in mind, and with its evident recovery due to a direct drainage from the meninges through the internal auditory meatus, through the internal ear, middle ear, etc., through an accidentally artificially created opening, the possibilities of a new labyrinth operation have made themselves apparent.

Before actually outlining the operation a few preliminary remarks might be in order.

*To be read at a meeting of the Otological Section of the New York Academy of Medicine, January 10, 1919.

First, the operation is intended as a radical measure, as a last resort in meningitis coming from infection through the labyrinth and infecting the meninges of the internal auditory meatus. It might be used as a last resort following the usual operation, for the relief of diseases of the labyrinth. These various labyrinth operations which I have in mind all bear very close relationship and have been variously outlined by other otologists, notably Jansen, Hinsberg, and in America Richards. These operations are intended, as I understand it, for the relief of purulent diseases of the labyrinth, and not as a means of draining infection from any area involving the meninges. If they are intended for drawing away infection when it has once reached the brain covering, thereby causing a meningitis, to my mind they are notably deficient. In fact, as I look at it, meningitis is very often due directly to the labyrinth operations here referred to. The technique of these operations is well known, I am sure, to all of you; but referring to them again in a general way, the substance of these operations consists in draining the labyrinth by opening up the various semicircular canals and then by taking away a part of the inner wall of the middle ear down to and covering the first turn of the cochlear, thereby draining the labyrinth. These operations are very often done after actual development of the meningitis. To my mind, they have little effect in relieving the meningitis, and their sphere of usefulness at its seat in the meninges and to drain it over as wide an area as possible, and I believe that the operation which I am about to outline will find a field not only for local involvement and the involvements of serous meningitis, but that it will have should absolutely be limited and demarcated as operations for infections involving the labyrinth and the labyrinth only. The advocates of this type of labyrinth operation all emphasize the fact that the operation must be done with extreme attention to detail, and that great caution must be used in removing the various layers of bone, so that the modiolus will not be injured and thereby cause a flow of cerebrospinal fluid, opening a passage directly to the brain. I repeat again, and strongly repeat, that the forms of labyrinth operation herein referred to should be limited strictly to the purpose of draining the labyrinth. When meningitis has taken place these operations are useless. The object then becomes to drain the point of infection

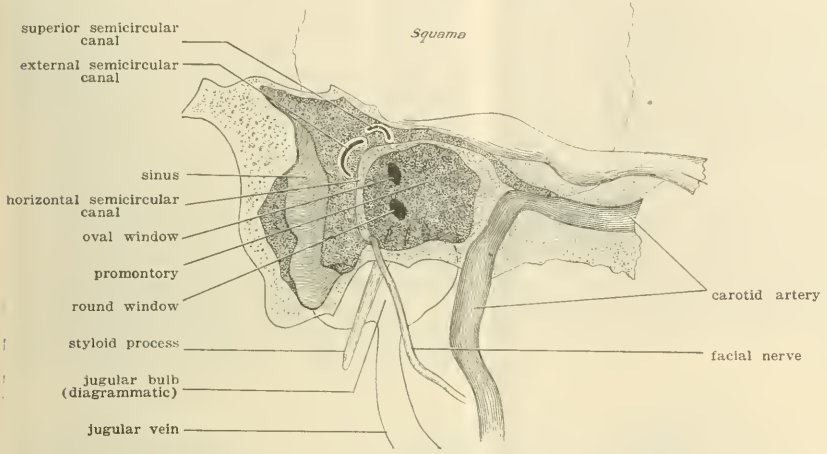

FIG. 1.—The normal bone.

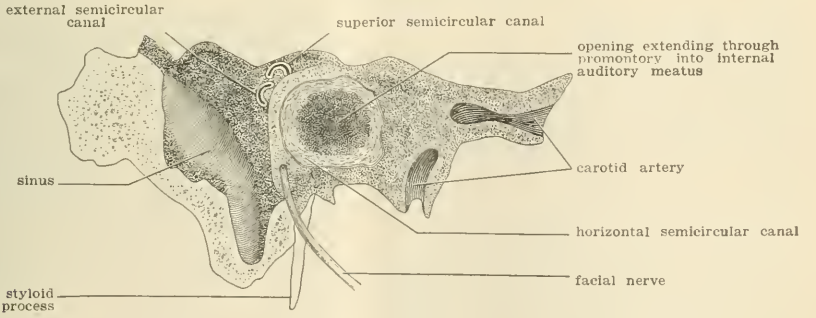

FIG. 2.—Destruction of the promontory and opening through into the internal auditory meatus.

a field for diffuse meningitis, even of a purulent character, if the area of meningeal involvement is not too far out of the area of drainage.

The only procedure that we have at the present time to combat meningitis of the type which I am now describing is the Neumann operation, which consists in working down on the posterior border of the petrous portion of the temporal bone, the object being to open into the internal auditory meatus. To my mind this procedure appears to be insufficient; it does not drain the area as intended, it is extremely difficult to do the operation well, and there is always great danger of fracturing off the petrous bone through the internal auditory meatus forward.

The object of my operation is to drain as wide an area of the meninges as possible. The meninges must be exposed over a large surface; the opening leading into the meninges must be large and the drainage directly out into the radical cavity, where the wound can easily be handled—not through a small opening, but through a large opening directly under the eye.

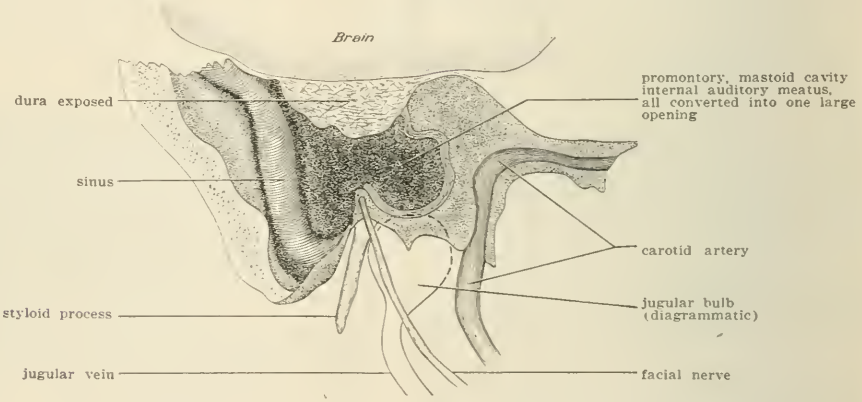

FIG. 3.—The completed operation.

Technique of the Operation.—First: Performance of the radical operation.

Second: The radical operation must be carried to its furthest limits; the facial ridge must be cut down to its very last shaving; the middle ear must be curetted till the bone surrounding it is extremely thin; in other words, the middle ear cavity must be enlarged as much as possible. The sinus should be exposed from above the knee, and exposed and followed downward toward the bulb as deep as possible. The bone in front of the sinus must be cut away as deep as possible, exposing the soft parts beyond; the dura outlining the middle cranial fossa above the middle ear should be exposed as deeply and as far forward as possible; in fact, the dura should be exposed over such an area that it will form a junction with the dura covering the sinus region, and the exposure should extend as far forward as the superior semicircular canal. The dura outlining the middle and posterior fossæ and covering the sinus should be exposed; the horizontal and external semicircular canals, and, if possible, the superior semicircular canal, should all be brought into view.

Third: The promontory is now opened, and a direct passage is made through it, so that the internal auditory meatus communicates through a direct passage with the middle ear. The modiolus and whole internal ear should be broken down, and this communicating path between the internal auditory meatus and the middle ear should be made as large as possible. When the modiolus is broken down, and the internal auditory meatus opened, there will be an escape of cerebrospinal fluid; the passage must then be packed tightly, as we enter upon the final stage of the operation.

Fourth and final stage: The bridge of bone now remaining between Trautman's triangle posteriorly, and the middle ear, which holds the facial nerve and the horizontal, external, and superior semicircular canals, should be broken down and absolutely destroyed; you have now exposed a large area of dura and have converted the anterior and posterior portions of the radical cavity into one large cavity. In other words, the brain is exposed over an area extending from the carotid artery in front to beyond the sinus behind, and the area of dura in the region of the internal auditory meatus has a straight passage for draining to the outside.

It seems to me, regarding this operation, that there would be two points of criticism: the first, the destruction of the facial nerve. This should be offset by the fact when you consider that this operation is indicated only as a last extreme measure to save life where death is practically certain; under the circumstances, the facial nerve should be sacrificed. The other objection might arise that opening of the modiolus causes a loss of cerebrospinal fluid; and that by opening the internal auditory meatus you open a direct pathway for infection to the meninges; but in this connection it must be remembered that the meninges are already infected, and that if infection cannot enter it also cannot escape. The destruction of the promontory and wide opening of the internal auditory meatus make possible drainage of this area of infection. This is a fact that cannot be denied.

Further, in this connection, and as regards the

escape of cerebrospinal fluid, I desire to call attention to the work of West & Scott, who describe an operation of drainage of this area by means of a wire drain. I discovered their work in reviewing the literature concerning this subject. I consider it of greatest importance that this radical labyrinth cavity be finally packed and drained by means of gauze. I mention this because of the fact that when gauze is used the tissues have something substantial around which to build and to demarcate the infection. A large quantity of infectious material is absorbed very quickly by gauze.

50 East Forty-second Street.

SYPHILIS IN 1918.

By B. SHERWOOD DUNN, M.D.,

PARIS, FRANCE.

OFFICIER D'ACADÉMIE; MEMBRE CORRESPONDENT DE LA SOCIÉTÉ OBSTETRIQUE ET GYNÉCOLOGIQUE DE PARIS; SURGEON TO THE SERVICE DE SANTÉ MILITAIRE DE PARIS; PHYSICIAN TO COCHIN HOSPITAL.

THERE follows in the train of every great war in history a notable increase in the venereal diseases, and the present war is no exception, other than that the percentage of increase in syphilis is unprecedented.

For the first time the American army is sent to European shores to battle in the cause of right and justice. The menace to the health of our troops in the ever-increasing percentage of syphilis found in every part of England and France would seem to make this an opportune moment to review the progress that has been made to combat this disease, and particularly the latest accepted, and, so far, most reliable remedies brought before the profession.

After my graduation from the medical department of the University of France I looked about me for some service in particular to follow, and attachd myself to the celebrated Fournier at St. Louis. Several months after the commencement of my service, at the close of the morning clinic, he reviewed the work of the morning, as was his habit, and concluded somewhat as follows: "Gentlemen, what is syphilis? We don't know. Where did it come from? We don't know. Can it be cured? We don't know. Has it ever been cured? We don't know." Much that I had encountered in the work before this had seriously discouraged me, and following this frank confession of the impenetrable mystery shrouding syphilis I hung up my hospital blouse and apron for the last time at the clinic of that great master and turned my attention to the field of gynecology, finally attaching myself to the service of that great master and savant, Richelot, who still lives and works, and whom I count among my oldest and most valued of masters and friends. Being incapacitated for further surgical work by the injury I received at the front, I was transferred to the medical service, and attached to the present great Fournier (Louis) in the syphilitic wards of Cochin Hospital, just as he was commencing the systematic proof of the value of the new remedy for syphilis, discovered by Danysz of the Pasteur Institute. Two years' experience with upward of 10,000 cases exhibiting every phase of this dread disease has fascinated me anew with the antiquity of its origin, mystery of its history, and terrifying consequences attending the neglect of proper treatment, not only to the subject, but to succeeding generations, typifying the law "I will visit the sins of the fathers upon the children unto the third and fourth generation."

With respect to present conditions in France, the lewd women from all parts of the interior have flocked to Paris, where they are the most likely to encounter the soldiers on leave, making this city a hotbed of prostitution, and General Pershing has recognized the danger, and made it difficult for men to visit Paris. In the genito-urinary clinic of Cochin Hospital, prior to the war, three out of every one hundred applicants for admission were affected with syphilis. Our statistics for 1917 show that twenty-one out of every one hundred are so affected. Professor Gaucher, who until his death a few months since was in charge of the clinic at St. Louis Hospital, said:[1] "Whereas before the war, in round numbers, out of 3,000 clinical patients 300 had syphilis, or 1 in 10, during the first months of the war these increased to 800 in 5,000, or 1 in 6. During the last eight months of 1916 this increased to 600 in 2,300, or 1 in 4. I therefore find that from August, 1914, to the end of December, 1915, the ratio of syphilis had increased more than one-third, and from January to August 1, 1916, it had increased more than one-half, and since then has advanced to almost two-thirds." (January, 1917.) By the report from Cochin Hospital in October, 1917, syphilis is shown to have increased seven times since the outbreak of the war.

It is only a few years ago that we thought we had come to a perfection of knowldge in the use of mercury and iodide that gave practical assurance of ability to control and subdue syphilis and give security to the patient from the effects of its ravages; the first-named remedy playing by far the most important rôle because of its proved activity at all stages of the disease, from the appearance of the chancre to the remote accidents of the teriary period; the iodide filling a well recognized requirement at every stage where is found cellular infiltration, from which are derived the gomma and sclerose conditions, and therefore most commonly employed in the tertiary stage. Outside of the "curative" properties of mercury, it was also recognized to possss certain preventive action not attributable to the iodide. The great Fournier was convinced, and taught, that mercury, and it alone, possessed the quality of prevention of relapse of secondary accidents, and that it alone, administered with perseverance over a long period, was capable of preventing the disease from advancing to the tertiary period.[2]

The preventive properties found in mercurial treatment were found most prominently presented in the new-born. Innumerable have been the records of cases where the infected father or mother has submitted to a prolonged mercurial treatment, the curative qualities of which were demonstrated by the birth of a healthy child, following a previous history of a series of miscarriages or death of the offspring at an early age as the result of hereditary infection.

Two methods have for a long time been recognized for the direction of the treatment: One very properly termed the "opportunist" the other the "pre-

ventive." The first was employed only when the symptoms of the disease manifested itself, and as a consequence was confined to the treatment of the disease in activity and lost all controlling influence over the latent condition. The treatment was discontinued with the disappearance of active symptoms and as a consequence the disease little by little made progress by stages to the period where the tertiary accidents were manifested.

Fournier who for a long time weighed and discussed the opportunist treatment, finally by weight of his great authority and influence secured the general adoption of his method of "chronic mercurialization," a series of treatments by this remedy, separated by regulated periods of repose. His treatment was governed by the following rules:

The hydragyric treatment ought to commence at once that the existence of a true chancre is recognized.

The treatment should at once be pushed to the most intense degree that can be supported by the patient, rapidly increasing the dosage to the limits of toleration.

No matter in what form the mercury is employed, metallic or salts, soluble or insoluble, the patient is submitted to an intermittent treatment, but successive, regulated as follows: The first and second years' treatment by mercury alone, for periods of twenty or thirty days; the first year repose of one month between each period of treatment; the second year, periods of two months of repose between each period of treatment. The third year, the iodide of potassium is added to the cure; giving one month of mercury followed by one month of iodide, followed by two months of repose. Maintained in that ratio during the year. The fourth and fifth years, two cures analogous to the above with two intervals of four months each.

Fournier in later years was struck by the frequency of refractory cases, giving evidence of secondary symptoms, after the five years of regulated treatment which had not destroyed the disease germ. Tormented by the failure of mercury to check the progress of the disease to the grave tertiary forms (tabes, general paralysis, leucoplakia), he counselled the continuation of the mercurial cure over the seventh and ninth years (corresponding to the most frequent evidences of these tardy accidents) by intensive application of frictions or by injection.

Marriage was considered unsafe until four years had elapsed since the patient was seized, and the disease had been subjected to at least three years of intensive treatment with mercury, there being a minimum of one year since the subject had exhibited any signs of the disease; and as an additional precaution a month's treatment should be administered prior to the wedding.

During the past few years all of these opinions and conclusions, based upon so many years of patient study and experiment, have been brought into question; the value of therapeutics heretofore employed, direction and duration of the treatment, together with many new problems attached to both, have been discussed with new vigor. It can be said that never has the therapeutics of syphilis had a greater number of students or been more persistently and passionately studied than in those years just preceding the war.

Three important factors have, in our judgment presided over the active researches made: (1) The discovery of the syphilitic parasite in 1905 by Schaudinn and Hoffmann. (2) The discovery of the seroreaction by Wassermann in 1907. (3) The new ideas of the liability and frequence of the infection revealed by the lumbar puncture and study of the cerebrospinal fluid. (Widal.)

The discovery of the treponeme and its study, established its analogy, more or less marked with the parasites of the order of the Spirilla. Ehrlich and his principal collaborator, S. Hata, for a number of years pursued with unflagging persistency the study of chemical bodies susceptible, on the one hand, of fixing upon these parasites, upon the chemioceptors of their protoplasma, and on the other hand, of a toxicity sufficiently feeble to permit of administration in destructive doses without injury to the human organism.

These experiments made upon recurrent fever (Ehrlich and S. Hata, Iversen, Bitter and Dreyer) upon the spirillosis of chickens (Ehrlich and S. Hata), frambesia (H. Nichols) showed that the best results were furnished by a series of arsenical agents: first, by the derivatives of phenyl-arsenic; later more remarkable results were furnished by other arsenical derivatives of arsenobenzol. Ehrlish and S. Hata commenced the experimental treatment of rabbits, inoculated with the syphilitic germ (keratitis, orchitis, syphilis of the scrotum), and secured the radical abolishment of these lesions by a single dose of dioxydiamino-arsenobenzol, and in 1910 it was presented to the profession as the savior of an afflicted race in the form of salvarsan. realizing by a single treatment the sterilization of the human organism infected by the treponeme (*therapia sterilisans magna*).

The Wassermann reaction then took place as the arbiter of the efficacy of treatment declaring whether or not the organism was freed from infection, the reaction being positive in presence of the germ, or negative where the germ remained latent or had been driven from the blood current and the subject was freed and pronounced cured. It also served in suspected cases to demonstrate the presence or absence of the infection.

In the presence of this great step in advance in the recognition of the malady, the empirical methods of treatment heretofore in vogue became obsolete. We are now in possession of a scientific means of determining at any moment when the subject is infected, the duration of the disease, when it reappears, and when the cessation is definitive.

The systematic practice of lumbar puncture in the subject of syphilis (Widal, Ravaut, Milian. Jeanselme and Vernes) permits the establishment of the frequency with which the nervous system, always immune during the primary stage, is invaded at the secondary period and chiefly in those who have submitted to no treatment up to the manifestations at this time; when found it presents most frequently in form of a latent meningitis, purely histological in character, at times expressing itself clinically in form of headache; very rarely may be found a type of acute meningitis; in any case, the alterations found in the fluid which normally is always sterile, consist in a hypertension more or less marked, albuminose (globulin) in quantity

equal to 20 grams, lymphocytosis of a variable intensity.

The prognostic importance of these early evidences is easily understood, if the later anatomopathological and clinical development of tabes and general paralysis has its beginnings (Babinski, Widal, Nageotte, Ravaut, Vincent, Sézary, Jolivet) in this histological meningitis.

The result of these additions to our knowledge has given rise to certain rules of procedure in the diagnosis, control, and cure of syphilis.

Put into action at the earliest moment possible, an energetic antisyphilitic treatment before the general infection of the patient has been realized, before the state of immunity has become established, and reinoculation by the chancre is possible, while the Wassermann test still gives a negative result, and the cerebrospinal fluid still presents no alteration, say within twenty days after the appearance of the chancre, permits us to hold out the hope to every patient of a radical and permanent cure and to realize it in a certain number of cases, the fact of which is proved by his or her reinoculation at a later period.

During the treatment the progress of the malady must be constantly recorded by the repeated examination of the blood, to the period where the Wassermann test gives a persistently negative result and the sterility of the cerebrospinal fluid, gives proof that the syphilitic infection has been completely driven from the system.

If we examine the different forms of medication employed to secure this result, by those authors whose extensive experimental studies and long years of practice lend to their opinions almost the weight of law, we find they are a long way from being in agreement. The number and variety of products that have issued from the German and French laboratories for the cure of syphilis during the past ten years are almost legion, and have built up a certain following in every instance, so much so that we can say that after the introduction into France in 1910 of the 606 of Ehrlich, the syphilographists have divided into two camps, one that supports mercury as the only safe, sane, and certain cure, the other equally as persistent advocates of arsenic as the only radical curative agent. Recently a third group has slowly and gradually been attracting public attention by the moderation but persistency of their published opinions favoring an eclectic treatment, combining both mercury and arsenic. In order that the reader may form an intelligent opinion of the merits of the present-day treatment of this dire malady, I want to lay before him a clear résumé of these three doctrines.

The agents actually employed in the mercurial treatment of syphilis are various, comprising the metal itself or its various salts, both soluble and insoluble. The methods of administration are equally various, but a certain number have fallen into disuse. Injection by the buccal route which at first was the rule, is now less frequently employed. Mercury was used in pill form (blue pill), in powdered form (gray powder, hydrarggram cum creta) the protoiodide in pill or powder (gram 0.10 per day), the bichloride in pill (Dupuytren gram 0.10 two and three times per day) the lactate (Gaucher). The administration by friction is now less employed, yet nevertheless in doses of 4 to 8 grams per day, thoroughly rubbed in, Neapolitan ointment, constitutes an active and powerful treatment and produces rapid results. It will ever remain an energetic means of treatment in acute cases. More especially in those exhibiting cerebral accidents.

Intramuscular injection constitutes to-day the favorite mode of administration. We use the soluble salts in daily injection or an insoluble product suspended in oil, injected every fifth or seventh day; this deposits in the tissues a provision of the remedy to be slowly absorbed by aid of the interstitial juices. All of these injections are made with great care as to aseptic precautions, using a needle 6 centimeters long, under the aponeurosis of the thigh, at well-determined points (points of Smirnoff and Galliot). Ordinarily these are made in two time; the needle is introduced the full length and if no blood appears by aspiration the syringe is adjusted and injection made.

The soluble salts most frequently employed are the benzoate (solution 1 in 100: 0.01 to 0.03 gm. pro die) the biniodide (aqueous solution 0.03 gm. pro die) the bibromide, which is, as a rule, accompanied by considerable soreness and pain (0.018 gm. per centimeter cube of solution) the cyanide (first used by the oculists and much employed for intravenous injection, every day or every two days in dose of 0.01 gm. per centimeter cube of distilled water).

The injection of the soluble salts has the great advantage of permitting an exact dosage, easily regulated following the indications in each patient. An objection which has been brought against them is that they demand great care and attention to secure expected results and avoid accidents of faulty administration; but the technique becomes a matter of habit with frequency of administration.

In the injections of the insoluble forms, mercury itself suspended in vaseline oil (gray oil) in the proportion of 40 to 100 of actual weight, represents 0.02 gm. of Hg. per division of the Pravaz syringe. Commercially there are syringes of the Barthelemy type which give 0.01 of Hg. per division. We inject each week 7 to 8 divisions, using as a rule dosage 0.01 gm. per kilogram of weight of the patient. Gray oil is a form of medication much favored at the present day; it is benign, free from many inconveniences attached to other forms. It is efficacious, but has not the intensive effect wrongly attributed to it by some authorities. It has the inconvenience of sometimes giving rise to pain and at times leaves at the seat of injection a nodule that remains painful for some time. It has been responsible for some grave accidents, even of death, and for this reason has created some irreconcilable adversaries. We will later consider these objections and their consequences.

Calomel suspended in vaseline oil or olive oil in proportion of 0.05 gm. per cubic centimeter injecting 1 to 2 c.c. per week furnishes a medication of superior activity. Unhappily it is as a rule very painful, giving rise at times to violent sciatic pains, not immediately, but the next day or the day following. An effort has been made to overcome this inconvenience by the addition of cocaine, guaiacol, orthoform (Duret), of camphor, of calomel of Zam-

belitti. It has been known to cause aseptic abscesses, free from pus, of a chocolate color.

The salicylate of mercury suspended in vaseline oil 0.066 gm. per cubic centimeter cube (0.5 c.c. dose, twice a week).

In addition to the criticisms we have cited, as made against the employment of the insoluble forms of mercury, there remains the fundamental objection that it is a blind treatment in which it is impossible to demonstrate with any certainty the amount or rapidity with which the injected material is absorbed and the clinical observations go to show that this process varies widely in different subjects.

The iodide of potassium is employed chiefly internally (solution of 1 gram to the tablespoonful) 2 to 10 grams in the twenty-four hours, largely diluted and taken with meals. With those who show gastric intolerance or difficulty in swallowing the mixture, it can be administered by way of rectal injection (2 to 6 grams in 200 grams of milk with 10 drops of tincture of opium, and finally by hypodermic injection (Bouchard, Bousseau) 0.50 gm. per c.c. repeated from 3 to 5 times in the 24 hours, 2 c.c. to the dose. These injections are more or less troublesome owing to the pain and lameness following them. As substitutes for the iodide there have appeared the iodipine of Merck 10 to 20 per cent. iodide, and the lipiodal of Lafay 40 per cent. iodide. Five to ten c.c. of these may be injected every two days.

The treatment of syphilis at the first appearance of the chancre, treatment as early and as intense as possible (for it seems to be well established that these two conditions have the most important bearing upon the future course of the disease), is best realized to-day by intramuscular injections (or in the employment of the newer remedies by intravenous injection). During the first six months of the malady the soluble salts of mercury are used (at first 0.01 gm., then 0.02, and then 0.03 gm. of the benzoate and the same of the biniodide) in series of twenty to twenty-five daily injections, with an interval of one month between each series. Some authorities employ the gray oil (6 injections weekly with one month between each series, in average doses of 7 to 8 centigrams of mercury). Duhot has carried the dosage to 0.12 to 0.14 gm. without accident. Calomel (0.05 to 0.10 gm. each week) has also been advocated.

At the end of the first six months of this treatment is commenced the continuing or sustaining treatment. Those favoring the continuation of the soluble salts recommend the continuation of twenty to twenty-five injections (benzoate or biniodide), increasing the free intervals from one month to six weeks and two months (four cures per year for the second and third years), practicing ten injections each month at first, then over a period of six weeks, and then two months.

The insoluble injections, chiefly gray oil, are advocated by a great number of practitioners for the supporting treatment; four cures of six injections for the second and third years, three for the fourth, and two for the fifth year. This practice is not prudent in the albuminuric and diabetic. The injections of calomel have generally been reserved for the active treatment of the rebellious cases and those exhibiting the graver accidents of the nervous system and for the lingual lesions (tertiary glossitis and leucoplakia).

The iodide of potassium has always been used in association with mercury in those cases presenting syphilomatous infiltrations and phagedenic chancre; in the secondary period, cephalgia, painful osteocopes, periostitis, arthralgia, myalgia; later of eruptions with infiltration into the tissues, gumma and gummatous ulcerations, visceral accidents at all stages, cerebral syphilis, tabes. In general paralysis it has been well shown that iodide of potassium not only has little or no effect, but that often it is harmful. The fallacy of administering iodides to the syphilitic as a spring and fall medicine for the remainder of their lives has also been abandoned.

The hygienic recommendations remain the same as ever: Abstention from alcohol and tobacco, provokers of mucous plaques, prolonging the contagiousness of the subject for years from a relapsing buccal condition slowly leading to sclerous glossitis, leucoplakia, and finally cancer, which is a too frequent complication, favoring the development of aortitis, hepatic cirrhosis, etc.

Syphilis of the nervous system is subject to a special hygiene: Avoidance of excess of either work or pleasure, ignoring which leads to tabes, general paralysis and the grave tertiary accidents.

As adjuncts to the mercurial treatment the mineral spring cures are always useful (and I am frank to say I am a great believer in water cures for many conditions). The sulphur springs (Luchon, Uriage, Allevard), in which conjunction mercury is remarkably well tolerated, and the water cures are particularly indicated in the cases of cerebral and medullary syphilis. For the tabetic the water of Lamalon, and for leukoplakia those of Saint Christian (douche filiforme of copper).

Following the initiatife of my former master and present friend, Professor Albert Robin, there has recently come into practice an intensive treatment by the benzoate of mercury in large doses. He has injected 0.05 gm. of this salt daily. Dufour has injected without accident 0.08 to 0.12 gm. twice a week. M. Bory[3] has employed a concentrated solution of 2 to 3 centigrams per c.c. of water, prepared at the moment of using, or still better, the preceding day. He injects daily intravenously or intramuscularly 0.04 to 0.05 gm. The intensive early cure of a syphilitic comprehends a series of twenty-five injections, being 1 gm. of the salt (equaling 0.44 gm. of mercury). The supporting treatment consists in making every fourth to fifth day injections in progressive doses of 0.07 to 0.08 gm. by series of six injections (a total of 0.32 gm. of benzoate of mercury). The first year a series of one month with two of rest; the second year, a series of one month with three of rest; the third year, a series of one month with four of rest. These large doses of mercury are well borne, provided the teeth have been put into a safe condition by proper dentistry. The patients exhibiting albuminuria have not been adversely affected. Bory claims that under this treatment the chancre cicitrizes as rapidly as under the treatment by arsenic. Whatever the future of this intensive treatment may be, it is certain that in the hands of those masters above noted it has given excellent results, and it deserves

to be more widely and thoroughly experimented with.

The advantages which Fournier claimed for the mercurial treatment, and for which he for so many years eloquently pleaded, are incontestably true, and the reader would find it a profitable expenditure of time to read his splendid exposition of the merits of mercury in his book, "Traitement de la Syphilis." Put under treatment upon the appearance of the chancre, and followed up vigorously and intensively, the majority of cases pass through the secondary period without the roseola or mucous patch. If they have been treated regularly and methodically during a series of years, the greater number, once they are "blanchis," present no accidents, the Wassermann tests remain negative, and their cerebrospinal fluid continues to be normal. When they marry they propagate healthy children who are born at term.

As against the advantages of the mercurial course, what are the accidents and disadvantages most frequently met with? The most frequent is stomatitis attendant upon the administration of the protoiodide, cyanide and inunction. Usually this complication is benign, and can almost always be avoided by putting the teeth into perfect condition before commencing the treatment. Diarrhea from the same cause can oftentimes be prevented and almost always controlled by tinctura opii camphorata.

More serious than these are the eruptions (mercurial), not the local forms occurring at the sites of the inunctions, but the general exfoliative erythroderma, happily infrequent, but sometimes provoked in certain subjects, no matter in what form the mercury may be administered.

Fatal results have been imputed to the mercurial treatment, but they are extremely rare, and usually follow treatment by calomel or gray oil injections, showing various complications—pulmonary embolism, toxic nephritis, stomatitis with extensive ulcerations, accompanied by intense salivation and loss of the teeth, necrosis of the maxillary, ulceration of the tongue, hemorrhage from the lingual artery (stomatite préhistorique de Fournier). The chief reproach made by the adversaries of the mercurial treatment is that in a proportion of cases which it has been impossible to determine, after five, ten or fifteen years the patient shows visceral symptoms of the tertiary period. But with the advent of the Wassermann test the oftentimes obscure origin of these serious symptoms has been clarified, and greatly multiplied the cases that can be directly attributed to syphilis as the causative agent. And since they have thus been determined, we have multiplied the number that have been relieved by a renewal of the treatment. Many have been the cases of aortitis, or heart lesions, or grave symptoms of the central nervous system that have been arrested or cured clinically and radioscopically. By means of injections of benzoate or biniodide, or intravenous injection of the cyanide combined with the iodide of potassium, oftentimes most excellent results have been secured. Since tabes has been recognized as being of specific origin and persistently treated as such, it is incontestable that its progress has been arrested and fixed, and we see now much less frequently than formerly this disease progressing to a condition of locomotor ataxia or general paralysis. Recently the experiment has been made of introducing the mercurial solution directly into the spinal canal (Sicard, Ravaut) in a maximum dose of a milligram. Edwards injected 0.0009 to 0.0013 gm. of sublimate once every two weeks, and secured in a number of cases the relief of the agonizing pains. Some authors have advised the intraspinal injection of the serum of the patient after the intravenous injection of mercury (mercurialized serum of Swift).

The tentatives made thus to introduce medication to the central nervous system in those suffering from general paralysis have given but little encouragement (Marchant, Duhot, Sicard). The psychiatrists believe this treatment not only useless but oftentimes harmful. Nevertheless, in the hands of certain authorities, good results have recently been obtained. Gaucher[5] has published two cases in one of which the history went back twenty years nearly cured by a prolonged mercurial treatment consisting of the injection of the benzoate, 0.02 gm., repeated for ten days with one month interval, followed by ten days of iodide in 2 gram doses.

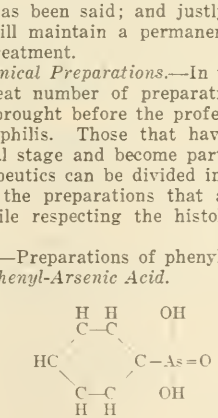
Recently Loeper, Bergeron and Wahram[6] have associated colloidal sulphur with mercury, injecting alternately the biniodide or cyanide and colloidal sulphur, and later mixing the two in the same ampoule. These authors obtained remarkable results in rebellious mucous cases, in cases of lesions of the cornea, arteries and kidneys, and also in cases of leucoplakia.

We can conclude that the mercurial cure, intelligently and faithfully applied, has an undoubtedly powerful influence in the arrest and control of syphilis, and this treatment is far from being abandoned, as has been said; and justly, mercury has won and will maintain a permanent place in the syphilitic treatment.

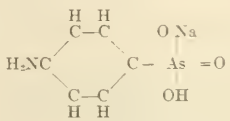
The Arsenical Preparations.—In the past fifteen years a great number of preparations of arsenic have been brought before the profession as a specific for syphilis. Those that have survived the experimental stage and become part of our recognized therapeutics can be divided into two groups, comprising the preparations that attack the treponema while respecting the histological cells of the patient.

Group A.—Preparations of phenyl-arsenic.

First.—*Phenyl-Arsenic Acid.*

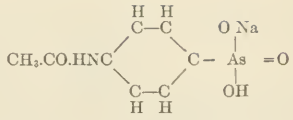


Second.—*Atoxyl.*



Sodium salts of para-amino-phenyl-arsenic acid, a preparation in which NH_2 replaces an H atom of the phenyl-arsenic acid.

Third.—*Arsacetine.*



a radical acetyl, $CO.CH_3$, replacing an H atom of the NH_2 in the preceding.

Fourth.—*Hectine.* Sodium salts of benzo-sulpho-paramino-phenyl-arsenic acid. Here are found two molecules of benzoate (the commencement of the arsenobenzol products), one molecule of sulphur, SO_2, replacing an H atom of NH_2 of one of the molecules of benzoate.

Among these diverse combinations, made chiefly of derivatives one from the other, two have been seriously tested in actual practice—atoxyl and hectine.

Atoxyl was experimented with largely by Salmon in 1902. It is a white salt which can be employed in pill form and by intramuscular and intravenous injection. The average dose (after Duhot) was 0.50 gm. per day for fifteen days. Salmon employed 0.50 gm. every second day during three weeks, followed by 0.75 gm. once with two days' interval, then 0.75 gm. once with three days' interval, and finally 0.40 repeated four times with intervals of three days between each dose.

It has an undoubted action upon the skin manifestations, chiefly the ulcerations; much less upon the mucous patches. Levy, Bing, A. Renault, Vedel and Duhot claim that it possesses no preventive action. It is far from being inoffensive. It is eliminated very slowly after a few days' injections, and the toxic effect of the accumulated drug has been frequently remarked (gastrointestinal troubles, vertigo). Following the treatment with this remedy late but definite blindness has been noted. At the present day it has fallen into disuse and is abandoned.

Hectine, discovered by Mouneyrat, is an excellent salt and but little toxic, although Balzer noted some passing trouble of vision following its administration, and also records some observations of increased sexual activity.

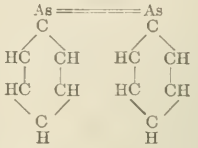
Hectine can be given in the form of a pill, 0.10 gm., once or twice per day during ten days; in the form of drops, twenty drops containing 0.05 gm. of the remedy, and from twenty to one hundred drops per day for ten days; by hypodermic injection, the hectine A. dosed at 0.10 and hectine B. at 0.20 gm. per ampoule of 1 c. c.; one injection every two days, then every day until twelve to twenty doses have been administered.

Each series of the remedy is followed by an interval of eight to ten days, and each cure comprehends 0.20 to 3 gm. of hectine. Certain authors have administered without accident as much as 4, 5, 6 or 7 grams.

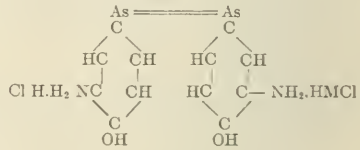
During the first six months of the syphilis a course of treatment is made each month. Following the indications of the case the intervals are lengthened, while the series of cures extend over four years.

Hectine has shown itself to be a benign remedy of moderate activity, comparable to gray oil. It seems to be particularly useful in the first stages of tabes, and I have known it to relieve promptly the agonizing pains which at times mark the invasion of the nervous centers.

Group B.—The Arsenobenzol Group. Arsenobenzol of Michaelis (1881).



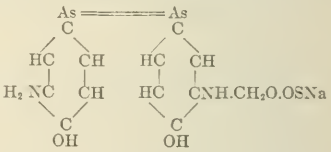
First.—*Salvarsan* or 606



(Ehrlich) (d'Hochst and Creil).

The French *Arsenobenzol* dioxy-diamino-arsenobenzol (employing the chlorohydrate).

Second.—*Neosalvarsan* or 914



(Ehrlich) (d'Hochst and Creil). The French Novarsenobenzol, or the Monomethylene-sulphoxylate of sodium.

Third.—*Luargol* or 102 of Danysz. Sulphate of dioxy-diamino-arsenobenzolate of bromide of silver and of antimony.

Fourth.—*Galyl* or 1116 of Mouneyrat. Tetraoxy-diphospho-amino-diarsenobenzene.

The discovery and employment of the arsenical group of anti-syphilitic remedies, some of which have not yet passed the experimental stage, promise to revolutionize the treatment of this disease, and have divided the authorities into two violently opposed camps. The clinical results attending the introduction of arsenic into our treatment have been of such a favorable character that their consideration and study are deserving of most careful review and comparison, of which the limits of this paper do not properly permit, and I defer their details to a later paper.

THE MEANING OF THE TERM "CRIPPLED"

By DOUGLAS C. McMURTRIE.

NEW YORK.

PRESIDENT, FEDERATION OF ASSOCIATIONS FOR CRIPPLES; EDITOR, AMERICAN JOURNAL OF CARE FOR CRIPPLES.

IN a recent bulletin appearing in the daily press and emanating from a government department there occurs the following statement:

> There exists a great deal of misapprehension in the public mind regarding the disabled soldiers. There are frequent allusions to the "crippled" soldier. There have been movements on behalf of various undertakings to "help educate the crippled soldier." They are all misnomers. The word "cripples" means those who have lost an arm or a leg or a hand. They comprise hardly 4 per cent. of the disabled.

Inasmuch as the terms "crippled soldier" and "war cripple" were widely used in some of the pioneer publications through which the earliest information on the subject was transmitted to the American public, the use of the designation "crippled" calls for some defence. There may also be taken vigorous scientific issue with the accuracy of the statement that the adjective properly is applied to amputation cases only.

The dictionary definitions which, after all, are of relatively slight importance as compared with usage and understanding, indicate that the cripple is one who is disabled (either from birth, or by accident or injury) from the use of his limbs; a lame person.[1] Another definition of the cripple is "a maimed or lame person or animal; one lacking the natural use of a limb or limbs."[2]

The definitions imply first the presence of limbs, with injury such as to limit their full and effective utilization. Amputation cases have by common use been included in the classification of the "crippled" but comprise a part rather than the whole.

The King James version of the New Testament, which is commonly regarded as being accurate in its use of English, does not refer to the cripple as an amputation case only, as witnessed by the following passage: "And there sat a certain man at Lystra, impotent in his feet, being a cripple from his mother's womb, who never had walked."[3]

There have been various scientific definitions of the term. At the German Orthopedic Congress in 1908 there was proposed by Dr. Konrad Biesalski and accepted the following:[4] "A cripple . . . . is a patient who, in result of congenital or acquired disease of nerves, bones, or joints, is handicapped in use of his trunk or limbs." Later, in 1915 the same authority defined[5] the cripple as "a person who has suffered permanent and serious impairment in freedom of movement of limbs, or in carriage."

According to the only official census of crippled children, which was made in Germany in 1906, there were shown to be 75,183 cripples under sixteen years of age, of whom approximately 93.5 per cent. were not amputation cases.

In Birmingham, England, a census of cripples, both adults and children, was taken in 1911. The definition of cripple adopted for the purpose of this study was "a person whose (muscular) movements are so far restricted by accident or diseases as to affect his capacity for self-support."

In the city of New York there are seventeen organizations which have the word cripple as part of their name. Not one of these deals exclusively or even largely with amputation cases. The majority of the cripples under their care suffer from tubercular bones or joints, hunchbacks, infantile paralysis, spastic paralysis, congenital deformity, rickets, malunited fractures, arthritis, and so forth.

In a survey of cripples in Cleveland, Ohio, one of the most careful pieces of scientific work in this field yet carried out in the United States, cripples were defined as those[6] "who are handicapped because they lack the normal use of skeleton or skeletal muscles." Of the cripples enumerated, well over three quarters of the total number were not amputation cases.

From another angle the classification of cripple is almost coincident with the scope of orthopedic surgery. The great majority of orthopedic cases are in common parlance termed cripples, and the range of orthopedics has widened rather than diminished during the present war. At the initiative of Sir Robert Jones, one of the world's leading surgeons, a large proportion of injured British soldiers were assigned for treatment to the division of "military orthopedic surgery." According to army instructions there fall to this division all surgery of the extremities, ankylosis of joints, deformities and disabilities of the feet, malunited and ununited fractures, injuries to the peripheral nerves, and conditions requiring the transplantation of tendons.

According to Sir Robert Jones, this specialty comprises a very large proportion of the injuries of war. Surely this authority knows the meaning of the terms used in his particular field. How does he designate the men under orthopedic care? In a recent statement, in speaking of orthopedic surgery he says: "Arising out of principles adopted for the treatment of *crippled* children, it has expanded into a huge organization of extreme military importance—first, with the object of receiving the serving soldier and sending him back to the fighting line; and, second, to reconstruct and restore the functions of those so badly *crippled* as to be useless as fighting units but who, if properly treated, may take their places as useful workers and efficient members of organized society."[7]

It is quite clear, therefore, that by dictionary meaning, by scientific definition, and by popular usage and conception, the term "crippled" could never be said to include the amputated only, and that a claim to this effect is inaccurate in the extreme.

It would not be claimed, however, that the term "crippled" covered with exactitude the condition of all the men discharged for invalidity, though it would be claimed that the designation of "crippled soldier" typifies to the public mind the permanent injuries incurred at the front. It is a term at once graphic and familiar and requires no long-winded explanation. As in the economic rehabilitation of invalided soldiers, en-

listment of the interest and support of the public is essential to the success of any national program, it is necessary to speak to the public regarding the subject, and speak in terms that will immediately be comprehended.

Is there any precedent for using the term "crippled" or some word similar to it in reference to the broader field of rehabilitating invalided soldiers in general?

In France, where re-educational provision for permanently injured soldiers had its first practical start, the movement has been popularly designated as for *mutilés*, which translates as "maimed" and denotes in particular the amputated soldier. But the term was a vivid one, which registered on the public imagination, and by usage has come to include practically all invalided soldiers. The state authority in France created to deal with the after-care of invalided soldiers is named the *Office National des Mutilés et Reformés de la Guerre.* Yet "mutilés" is of much more limited scope than "crippled," the equivalent of which in French is *"cstropié."*

The official description[1] of the splendid institution for invalided Belgian soldiers, located at Port-Villez, France, speaks of re-education for soldiers "maimed and crippled."

In Germany the work was designated from the first month of the war as *"Kriegskrüppelfürsorge,"* or the care of the war cripple. The public education documents which were circulated by the thousands in the early months of the war carried titles including the word *"krüppel."* Other terms have been used, but the early one sticks in the memory. And the leading journal which has published material on the work is one of *"Krüppelfürsorge."*

In Italy the first organization of national scope interested in the after-care of invalided soldiers was entitled the "Federation for Blind, Lame, and Maimed Soldiers." Blinded and orthopedic cases only were referred to, though the inclusion of other cases was of course assumed.

In the United States the first literature on the re-education of the injured made its appearance in 1911 and 1912. The term "crippled" was used in these articles being translated from the Danish *"vanfore"* and the French *"estropié."* From that time on, the usage continued. The only journal in this field was designated as being devoted to the "care of cripples." And finally the first articles to be published in America describing the reconstruction of invalided soldiers abroad appeared in 1915, and for the most part used the term "war cripple" in approximate translation from the French and German. The earliest official and public reference to the subject was an article from the Office of the Surgeon-General, U. S. Army, and entitled "The Passing of the Cripple."

So much for the matter of precedent. Another objection which has been raised to the use of the term "crippled" is that it is objected to by the men, and if applied will cast upon them an implication of opprobrium. There is room for wide difference of personal opinion on this point. The invalided French soldiers evidently do not feel this objection to be valid for they have named their own organization by a still narrower term, the *Association Générale des Mutilés de la Guerre.* In our own receiving hospital at Ellis Island men refer jocularly to a fellow invalid as "you confounded cripple." At the military orthopedic hospital at Toronto there is evident no special aversion to the word.

But from a broad point of view we should not shrink from using the word "crippled" where it accurately describes a case or class. There have been cripples always with us, there exist a great number at the present time, and there will be still more in the future. Name or rename as we may, the man who is lame, paralyzed, amputated, or hunchbacked will continue to be known in the public mind as crippled. Are we to pass the matter by, granting the crippled condition as half shameful, or are we, by a vigorous campaign of public education, to dignify it—to teach the people that to be crippled is not necessarily to be helpless, and that to be crippled and capable and useful is something to be proud of rather than ashamed? We owe it to the cripple to dispel the present illusions on the part of some people regarding his condition.

With the varying character of war injuries, however, the term crippled, while satisfactorily denoting the rehabilitation work to the general public, is not exact since it does not accurately apply to lung diseases, deafness, blindness, kidney troubles, mental disturbances, and the like. To cover these cases as well as the crippled many different terms have been proposed. By all odds the most successful and apt from the lexicographical point of view is "invalided," represented for example in the name of the lately re-christened "Invalided Soldiers' Commission" of Canada, which was previously the Military Hospitals Commission. In France the only school under national auspices is titled the "Institut National des Invalides de la Guerre." In Italy the new government department to look out for the interests of returned soldiers is called the "Opera Nazionale per la Protezione ed Assistenza degli Invalidi della Guerra," and in like wise the association of Italian invalided soldiers has taken the name of "Associazione Nazionale degli Invalidi della Guerra."

In Germany the term "Kriegsinvalidenfürsorge" has been used to a limited extent. In Austria it has been applied to a much greater degree, and in Hungary the designation is almost universal, the national authority being known as the "Office for Invalids."

The word "invalided," however, while familiar in England and the British dominions, is not in the least American and, by reason of its euphonic drawbacks, will in all probability not be adopted here.

The term other than *"Kriegskrüppel"* which is finding considerable adoption in Germany is *"Kriegsbeschädigten,"* or war injured. It is an all-inclusive designation which meets all requirements. Represented in the title of the imperial committee concerned in co-ordinating local work for invalided soldiers, the "Reichsausschuss der Kriegsbeschädigtenfürsorge," it also appears in the name adopted by the war invalided them-

selves for their association: "Verband der Kriegsbeschädigten."

The next term to be proposed and to meet with considerable acceptance is "disabled." It has been used principally in Great Britain where the Ministry of Pensions always refers to the "treatment and training of disabled soldiers." It has been used further in the practice of the Canadian authorities, and it is now being adopted by the various official and semi-official agencies concerned in the restoration of the invalided American soldier to civilian life. "Carry On," a magazine published for the Surgeon-General of the Army by the American Red Cross is stated as dealing with the "reconstruction of disabled soldiers and sailors." The Federal Board for Vocational Education refers to its responsibility as the "re-education of disabled soldiers and sailors." A recent manual of the Red Cross is entitled "After-Care of the Disabled Soldier and Sailor."

In one sense the term may be regarded as of similar significance to "Invalided." Accurately, however, disabled has an economic and practical implication. A man may be taken in by a re-education school "crippled and disabled" or "invalided and disabled" but he should be turned out "crippled and able" or "invalided and able." In the strict sense a writer who returns with a paralyzed left arm is crippled but he is certainly not disabled for he can return unhandicapped to the pursuit of his vocation.

In view of present circumstances and influences the term "disabled soldier" may wisely be standardized in the usage of those concerned in rehabilitation work. But the term "crippled" has much to justify its use, and should certainly not be confused by inaccurate definition.

A CASE OF ABDUCENS PARALYSIS COMPLICATING MASTOIDITIS: BRIEF DISCUSSION OF THIS COMPLICATION AS AN INDICATION FOR SURGICAL TREATMENT.*

By PHILIP D. KERRISON, M.D.,
NEW YORK.

Miss P. S., a girl of 11 years, was referred to me June 6, 1917, with the following history: Two years previously she had been operated upon for mastoidectomy, left, and had made a satisfactory recovery. Some five weeks previously she had developed acute purulent otitis media of the right ear for which she had been under treatment by an out-of-town aurist. While the acute symptoms had subsided, the aural discharge had persisted. The drum membrane also had fared badly, the membrana tensa having undergone rather extensive disintegration. Some ten days before she came under my care, she had suddenly developed distressing diplopia. Dr. John M. Wheeler, to whom she was referred on account of this symptom, made a diagnosis of abducens paralysis with resulting incompetence of the external rectus muscle.

When she first came to my office the patient wore a cover over her right eye to relieve the discomfort incident to double vision. On removal of this, it was found that objects, *e. g.*, one's finger, held in front of her were seen double when moved from the median plane of vision to the right. Moving one's finger in front of her to the right and asking her to follow it with her eyes, the left eye did so normally, the right stopping in the median position.

Examination of the right drum membrane showed a large oval perforation, comprising rather more than a half of the posterior segment of the membrana tensa. The tympanic cavity was filled with a thick, transparent fluid, which was exceedingly difficult to remove either by irrigation or by cotton on applicators. There was no appreciable mastoid tenderness.

On June 13, no improvement having occurred either in the tympanic or ocular symptoms, an operation on the right mastoid was decided upon.

Operation.—The right mastoid was opened by the usual method and revealed a mastoid of pneumatic type the cells of which contained some fluid pus; but there were no evidences of extensive bone disease. Some granulations clogged the aditus and tympanic vault. A careful mastoidectomy was performed, and this operation was extended in the following directions: the dura in the middle fossa of the skull was exposed by removal of the tegmen antri; it appeared perfectly normal. Exposure of the sigmoid sinus showed a perfectly normal dural covering. The dura over the cerebellum was next exposed by removal of the inner plate in front of the sinus. Careful inspection of these various regions did not reveal any gross pathological changes which would throw light on the ocular symptom.

Two days after the operation, the function of the right external rectus muscle was greatly improved. On the following day (third after the operation) Dr. Harmon Smith examined the patient with me, and we could find no abnormality in the movement of the eyes. From this time her eyes have seemed perfectly "straight" in whatever direction she looked. I regret that Dr. Wheeler did not see the patient until December 10, when he reported that the movement of the right eye was quite normal.

While it is an easy matter to theorize as to the various pathways by which an extension of disease from an infected mastoid may involve the 6th nerve, to find in actual practice a convincing hypothesis to fit the particular case may be difficult or impossible. Thus is said, partly on theoretic grounds, that the nerve may be compressed within that vessel in cavernous sinus thrombosis or disease; that it may be subjected to pressure in the posterior fossa by a thrombosed and inflamed inferior petrosal sinus (Page's case); that it may be involved in disease of the apex of the petrous bone (Gradenigo); or that the nerve sheath may be involved in a meningitis originating in a focus of infection over the mastoid roof (tegmen antri) and extending inward along the floor of the mid-cranial fossa; or that the nerve may suffer indirectly through a suppurative labyrinthitis, this giving rise to infection or inflammatory changes in the meninges in the posterior fossa.

These various hypotheses are theoretically sound and interesting, but in actual practice throw little

*Read in part before the Otological Section of the New York Academy of Medicine on March 8, 1918

or no light on the pathologic aspects of a given case. It may even be said that in the great majority of cases successfully operated upon, the exact mode of involvement of the 6th nerve is never determined. Gradenigo's symptom complex (severe frontal headache with eye pains or facial neuralgia, and with homolateral middle-ear or mastoid infection and 6th nerve paralysis) is said to point strongly to necrosis or at least disease of the apex of the petrous bone. But it must not be forgotten that middle-ear suppuration with abducens paralysis may coincide with ethmoid or other accessory sinus disease which might easily supply the sensory components of this syndrome.

In places where anterior poliomyelitis is epidemic or endemic (as in most large cities) it must be remembered that paralysis of the 6th nerve may occur as the single manifestation of this disease. I am told by Dr. Gover, assistant resident physician of the Willard Parker Hospital, that in recent epidemics several such cases have been observed there. A most thorough and interesting review of the literature of this subject up to that time was published by Dr. C. E. Perkins in 1910. Among cases analyzed were four (Perkins', Kopetsky's, Mann's, Alt's) in which complete disappearance of the paralysis occurred within 2 to 9 days after the mastoid operation. In the other cases reported the time of recovery was either not given or longer. In the case here reported the eye was functionally normal in 3 days.

Perkins collected from the literature 29 cases of mastoiditis with abducens paralysis in which the mastoid was operated upon, and 31 similar cases which were not operated upon. Of the former group, there were 1 death, 1 failure (*i. e.* of recovery from the paralysis) and 27 complete recoveries. Of the 31 cases not operated upon, there were 4 deaths, 3 failures, and 25 (sic) recoveries. From these figures, the logical deduction would seem to be as follows: In mastoiditis associated with abducens paralysis, the mortality is much greater and the percentage of 6th nerve recoveries is much less in cases not operated upon than in those in which the mastoid is operated upon. Therefore the occurrence with suppurative mastoiditis of paralysis of the external rectus occuli of the same side should be regarded as a positive indication for the mastoid operation.

Should the 6th nerve lesion be merely coincident and unrelated, the mastoid operation will serve only in eliminating the middle ear or mastoid disease. On the other hand, should the abducens involvement be the result of a spreading infection from the mastoid, a mastoid operation may be absolutely necessary not only to bring about restoration of the nerve function, but also to save the patient's life.

58 West Fifty-sixth Street.

Health of Brazil.—The famous saying "Brazil is a vast hospital" is in a fair way of being outlawed. Yellow fever is stamped out and the Government has made an immense appropriation for supplying prophylactic quinine to the entire community. To these achievements must be added the labors of the Oswaldo Cruz Institute in the realms of scientific prophylaxis of communicable diseases of all kinds.—*Brazil-Médico.*

OBSERVATIONS ON GAS POISONING.*

By EGBERT GUERNSEY RANKIN, M.A., M.D.,
NEW YORK.
RECENTLY OF THE GENERAL MILITARY HOSPITAL, COLCHESTER, ENGLAND.

Without having kept any accurate record of the gas cases which I have had under care in this hospital, I should say, there were about 60 in all. They were of two types, the "mustard gas" and those of the chlorine group. The former were more numerous and presented the following symptoms: extreme irritation of the eyes, a conjunctivitis with intense photophobia and lacrymation, both of which in their intensity seemed out of proportion to the degree of local inflammation. Other promnient symptoms were staining of the skin and burns. The skin in certain localities of the body was stained a sort of brown or khaki color. It seemed as if it were seared, later the epidermis would peel off in fine scales leaving a lighter similar stain which I believe gradually faded in time. This searing of the skin was not general but was confined to certain areas of the body, notably the back, abdomen, chest, and sometimes the legs. It appears to have been on parts which were moist.

As to the burns they were superficial as a rule, but sometimes involved the entire skin; they were observed on the back, legs and especially the scrotum, the axilla was seldom burned, doubtless because of its being almost closed to atmospheric influences. Parts that were moist or wet seemed to be those involved in the burning.

In many instances there was severe irritation of the pharynx and larynx causing a sensation of soreness and hoarseness and in the latter instance complete loss of voice. The lungs appeared to have suffered to a comparatively mild degree in most instances, occasionally however bronchopneumonia developed.

The face in some cases partook of the staining or searing—in one case now under my care it is quite severely burned. In some instances the nasal mucous membrane was also involved, causing a decided coryza with soreness and ulceration of the nares.

Gastric, precordial, and myalgic pains in various portions of the body were also present. The most persistent symptoms, however, and the last to disappear were the irritation of the eyes and the photophobia.

In regard to the chlorine gas group of poisoning, the chief organs to suffer were the lungs. There was a sense of oppression with dyspnea, soreness of the chest, and asthmatic breathing.

The physical signs were those chiefly observable on auscultation, and were mucous râles, also sibilant, together with much wheezing such as characterizes bronchitis and asthma. The expiratory murmur was prolonged, suggesting pulmonary emphysema, the percussion note, however, seemed negative and the characteristic barrel-shaped chest was absent for obvious reasons. Severer types resulted in decided broncho-pneu-

*Report to Col. A. P. Swanson, Chief Officer of the Medical Division, General Military Hospital, Colchester, England.

monia, but most cases we have had here have been those which were comparatively mild and which had been gassed from one to three weeks previously. There was a persistent irritating cough with scanty expectoration, which was a source of considerable distress to the patient.

The heart action in some cases seemed to have been impaired, there being decided increase of the pulse rate; gastric irritation was also present in some, also again precordial and myalgic pains in various parts of the body, which were often of a very persistent character. The ultimate result in the more decided types appeared to have been pulmonary emphysema with the usual asthmatic symptoms which persisted and resulted in permanent invalidism, unfitting for active service.

The treatment of the mustard gas cases was boric acid and borax solution for the eyes, followed by adrenalin chloride. For the burns, picric acid solutions, hydrogen peroxide, and dusting powders according to conditions. For the cough and laryngeal symptoms, heroin; for the throat, solutions of potassium permanganate. The myalgic pains received the salicylates and asperin.

In the chlorine gas cases heroin per os appeared to have been the most successful; the same line of treatment mentioned above was followed for the various myalgic pains.

Medicolegal Notes.

Revocation of License—Sufficiency of Complaint—Testimony of Accomplices in Unprofessional Conduct Case.—Appeal was taken from a judgment affirming the proceedings and determination of the California board of medical examiners revoking the license of the defendant (petitioner in the Appellate Court) to practise medicine on account of a violation of California St. 1915, p. 158, § 12, subd. 1, by attempting a criminal abortion. The district court of appeal held, over the defendant's objection, that the act is constitutional. The particular ground of the objection was that powers are conferred which belong strictly under the Constitution to the judicial department. Acts of the nature here under consideration have been repeatedly sustained as a proper exercise of the legislative grant. Various boards performing legislative and ministerial functions have the incidental and necessary power, sometimes referred to as quasi judicial, to determine facts and enter their judgment thereon; such as boards of supervisors, boards of equalization, boards of police commissioners, and many others unnecessary to name. Referring specially to medical acts, it is said in Hewitt v. Board of Medical Examiners, 148 Cal. 590, 84 Pac. 39, 3 L. R. A. (U. S.) 896, 113 Am. St. Rep. 315, 7 Am. Cas. 750: "Legislation of the character embraced within the general scope of the act in question in so far as it provides for the revocation of the certificate of a physician * * * is sustained upon the ground that the Legislature has authority under its general police power to provide all reasonable regulations that may be necessary affecting the public health, safety, or morals, and with this object in view to provide for the dismissal from the medical profession of all persons whose principles, practices, and character render them unfit to remain in it. As the duty of determining whether such professional or moral unfitness exists must necessarily be vested in somebody other than the Legislature, it is usually committed by appropriate legislation to boards composed of men learned in their profession."

The principal contention made, however, was that the complaint filed before the board of medical examiners was insufficient in its statement of facts to sustain the determination based thereon. The complaint read that the defendant did "aid and abet and attempt, agree and offer to procure a criminal abortion upon a pregnant woman, to wit," etc. The court held that this charge was phrased exactly in the language of that portion of the act defining the particular unprofessional conduct of which it was charged the defendant had been guilty. Counsel for the defendant argued that because the statute refers to a "criminal abortion," and that because in order to determine what a criminal abortion is one must look to the State Penal Code, the charge would be insufficiently laid unless the acts defined in the Penal Code as constituting the crime of abortion are set forth. The court said that the defendant was not charged with a crime, nor was he subject, upon the adverse determination made, to any penalty except the revocation of his license to practise medicine and surgery. The contention of counsel would have been entitled to more serious consideration had a criminal offense been under consideration with its attendant penalties, as that is understood under any of the penal laws of the State. Where an indictment or information is drawn under the Penal Code, it must, of course, comply with the provisions of section 950 of that Code, in that it must contain "a statement of the acts constituting the offense, in ordinary and concise language." No similar provision appears in the medical act. The court considered the language of the statute sufficiently explicit to advise a person charged thereunder of the particular kind of unprofessional conduct which it is proposed to prove against him and that was all that is required. The defendant cited a case where the Supreme Court of Oregon held a complaint before the medical board to be insufficient, because not alleging sufficient facts (Board of Medical Examiners v. Eisen, 61 Or. 492, 123 Pac. 52). There a case was presented under a law different from the California statute. In the decision it is recited that: "Before a license can be revoked by said board for unprofessional or dishonorable conduct under the provisions of this act a complaint of some person under oath must be filed in the office of the secretary of said board, charging the acts of unprofessional or dishonorable conduct and facts complained of against the licentiate accused, in ordinary and concise language." That provision which finds place in the Oregon law is practically identical with the provision of section 950 of the California Penal Code.

Another contention was that there was no legal or sufficient evidence authorizing the medical board to make the order complained of. The force of that objection rested chiefly upon the assertion that all the material testimony furnished against the defendant was that given by accomplices. The action not being criminal in its nature, the court held that the statutory mandate that a person may not be convicted upon the uncorroborated testimony of an accomplice had no application. Any witness whose testimony as to competent facts was convincing to the board engaged in the hearing of the charge would be legally sufficient. The evidence was held to warrant the revocation of the defendant's license.—Lauterman v. Anderson (Cal.), 172 Pac. 625.

Supersensitiveness of Patient's Skin to X-Rays.—In an action for damages for personal injuries alleged to have been inflicted upon the plaintiff by the negligent application of x-rays to his body the facts were that the plaintiff was severely burned while being treated professionally by the defendant, who was a practising physician and an expert in treating skin diseases with the x-ray. The controlling issue of fact made by the evidence was whether the injury was caused by one or more of the acts of negligence alleged by the plaintiff or whether the injuries were suffered because the plaintiff's skin was supersensitive to the x-ray current. On appeal from a judgment for the plaintiff it was held that a physician is not required to take precaution against a peculiar temperament or abnormal idiosyncrasy of which he had no knowledge and for detecting which there is no means. The evidence showed that the defendant did not know of the plantiff's supersensitiveness, and that there is no way to ascertain such a peculiarity prior to the treatment. It was held that the jury should have been told in appropriate language that, if they believed the proximate cause of the injuries to the plaintiff was his abnormal hypersensitiveness, but for which the injury would not have occurred, a verdict should be returned for the defendant; and the judgment was reversed.—Hamilton v. Harris, Texas Court of Civil Appeals, 204 S.W. 450.

Military Medicine.

The "Barbed Wire Disease" in War Prisoners.—Under the names "Stacheldrahtkrankheit" and "psychose de fil de fer" a peculiar psychosis of war prisoners has been described which is international in type, as shown by its identity in all races represented in the prison camps. A Swiss medical man, Vischer, has described it in an article reviewed in the *Correspondenz-Blatt* for Sept. 28. The psychoses of prisoners have been frequently described and the general motivation as well as the types are analogous, but in these war prisoners the barbed wire fences act as a red flag to a bull. Prisoners themselves have coined the terms above stated. There is a period of latency before the barbed wire disease develops. At first after internment there are peculiar reactions due to shutting off the outside world and mingling in close communion. The phase is one of stimulation. Men argue, become quarrelsome and envious, egoism is fostered. There is a rage for games. Gradually the picture changes to one of depression. Especially among the more finely organized a state of apathy develops. One is no longer able to concentrate on anything. Even music becomes undesirable. The mental state resembles in some ways the so-called cafardism which was first noted before the war in the French foreign legionaries, and thus perhaps light is thrown on the motivation of that mysterious affection. Sleep is disturbed by dreams and there is an abnormal sensitiveness to sounds. Only a small percentage remains quite immune. The barbed wire acts throughout as the badge and symbol of servitude. Even after release and internment in Switzerland the psychosis shows its presence. The part played by the wire appears to be shown by the fact that prisoners who work in small squads in the open under guard do not develop the disease. The well read author sees analogies of the "barbed wire disease" in Napoleon's life in St. Helena, in Stanley's prison experience, in Dostoyewsky's Siberian convicts, and especially in the polar explorer's mental state, as recorded in many diaries.

Urinary Spirochetosis in the Army.—In 1914 Japanese pathologists found a spirochete to be the cause of infectious icterus and late in 1916 the first cases of this malady were observed in France. Among the clinical expressions is a spirochetosuria, for the condition being a sepsis the organisms in the blood are eliminated in the urine. However, just as typhoid fever, which resembles it in many ways, may be localised in the kidneys, so in this affection the clinical expression may be a nephritis. In the *Journal de médecine de Bordeaux* for September, 1918, Charles describes six cases of this type. An analysis of these conjoined with cases seen by others shows that more than one type of nephritis is in evidence. The first resembles an ordinary acute nephritis and it was in following up one of this type that the authors discovered after the subsidence of the acute symptoms the presence of the spirochete in the urine. In five such cases there were edema, albuminuria, hematuria, and uremia, while icterus was absent. These symptoms, even when present in aggravated form, may suddenly subside with few or no consequences. Such behavior is not encountered in ordinary nephritis from exposure. It is still an open question what part has been played in alleged war nephritis by this spirochete. In a second type of case, represented by three patients, the disease expressed itself as a hematuria. Finally, and purely by chance, a simple spirochetosuria was encountered. Two patients presented this type. While all of the patients recovered irrespective of type there was generally remarked a prolonged subsequent period of debility. The one constant symptom in the nephritis was hematuria. In the spirochetosuric cases there was even a microscopic hematuria. This point is of practical significance, for every hematuria should be a signal for a search for the spirochete.

Injection of Alcohol for the Relief of Causalgia from Gunshot Wounds.—It was the late Weir Mitchell who gave the name "causalgia" to the acute and distressing suffering caused by injury to the median nerve in the upper extremity, on the internal popliteal nerve of the leg. According to Capt. E. Farquhar Buzzard, in a paper published some time ago in the *West London Medical Journal*, patients suffering from median or internal popliteal causalgia may be counted among those who suffer the most distressing results of modern warfare. Moreover, men with such injuries are apt frequently to gain little sympathy, for by nurses and even by medical men, they are regarded as highly neurotic subjects who are too greatly inclined to make the most of their injuries. However, as Buzzard points out, when a large sensory nerve is injured, stimuli of all kinds, physical, psychical, auditory, and visual, can give rise to spasms of intolerable pain. This being so, it is obvious that a main object of treatment is to give relief, permanent if possible, at any rate relief from such excruciating agony. The first principle is rest, mental and physical, and isolation or partial isolation, when this procedure can be carried out.

The resort to drugs is extraordinarily unsuccessful and is also to be strongly deprecated because of the risk of destroying what little morale the patient may have preserved.

Accordingly Buzzard adopted the following line of treatment. He explains to the patient that the pain is due to a partial injury of a nerve, and that he has some cause for thankfulness that the injury was not worse. Palliative measures, the application of heat or cold or of liniments containing camphor, menthol, chloral hydrate, etc., are used during the day, and at night a sufficient amount of sleep can be secured generally by the use of bromides or other mild hypnotics. But there remains a minority of patients whose suffering is so great and so prolonged that further steps must be taken. With such patients Buzzard has had the most gratifying results from the injection of alcohol into the injured nerve on the proximal side of the injury. A few drops of 80 per cent alcohol in acute cases of causalgia of the median or popliteal nerves will often altogether relieve the pain. Of course, there is the risk of destroying or greatly impairing nervous function, but in some cases in which this mode

of dealing with the situation was adopted function improved. Also the fact must be taken into consideration that median injuries of any degree of severity are followed rarely by complete recovery of function, and especially when the patient has endured a long period of intense suffering.

Carbon Tetrachloride Vapor as a Delousing Agent.—Now that it has been practically proven that at least one disease is conveyed directly or indirectly by body lice, it is a public health measure of the utmost importance to prevent these insects from gaining access to the body. With this end in view several methods of delousing have been given a trial, some of which have shown themselves effective. For example, dry and moist heat and hydrocyanic gas fulfill the purpose of destroying body lice on clothing excellently. At the same time the apparatus by which these methods are used is cumbrous and complicated and thus not always available for troops in actual warfare. Moreover, the need sometimes arrives of cleaning lousy clothing in jails, small hospitals, asylums, camps, and even in the home. Therefore, a simple means of accomplishing this object is desirable.

Dr. M. H. Foster, Surgeon, U. S. Public Health Service, in the search for some practical method of exterminating lice which would require only a simple apparatus, has been investigating the effects of carbon tetrachloride vapor and has described the results in Public Health Reports, October 25, 1918. Carbon tetrachloride is a heavy, colorless fluid, is extensively used in fire extinguishers and so on, and is also the chief constituent of certain proprietary cleansing fluids on account of its great power to dissolve fats. The vapor is heavy and instantly extinguishes combustion. Up to the present time it has not attracted much attention as an insecticide, but appears to be very toxic for flies, ants, potato bugs, and lice. The effect of this vapor was contrasted by Foster with that of gasoline and chloroform with respect to its effect on flies. It was found to be much more toxic than either of the other two. The effect of the combination of gasoline and carbon tetrachloride vapor was determined, the proportion being 1 part of gasoline to 2 parts of carbon tetrachloride. The vapor from this combination was not inflammable, but the mixture was by no means so efficient as the same amount of carbon tetrachloride.

Having in view the delousing of soldiers' clothing in places where complicated apparatus could not be obtained, the following method was thoroughly tested: A 10-gallon can, such as is used for shipping liquid disinfectants, was obtained. This can was 12 inches in diameter, 19 inches high, sheathed with a light wool covering, and weighed 6½ pounds. The top was cut out so that clothing could be introduced and removed readily. In making the tests the complete clothing of a United States Army private was placed in the can, each article being firmly rolled up. A soiled shirt, badly infested with lice, was cut into four pieces. Each piece of the shirt was rolled fairly tightly and then further wrapped in two thicknesses of ordinary sheeting; one piece of this material containing 90 live lice was lightly wrapped in the breeches and placed near the bottom of the container, another holding 98 live lice was tightly wrapped in the middle of the blouse and packed near the top of the contents. The complete outfit of wearing apparel was placed in the tin and pressed down rather firmly, occupying a little more than one-half of the total space. Several layers of filter paper were laid on top of the clothing, and on this paper 25 c.c. of carbon tetrachloride was poured. The top of the can was covered by several thicknesses of toweling and a loose cover placed over this, the idea being to protect the can from the effects of drafts, but not to seal it hermetically so as to permit some of the air to escape at the top when it was displaced at the bottom by the heavy vapor. At the end of two hours the can was opened, the package containing the lice infested shirt was aired and examined. All the lice were found to be dead and they did not revive when examined at various periods up to 24 hours afterward. It was ascertained that exposure under similar conditions to the same strength of carbon tetrachloride for an hour and a half was not sufficient to kill all the lice, about 25 per cent. surviving. It is essential that the container should be airtight, that it be only two-thirds full of clothing, and that it should be about twice as high as it is broad, as the vapor appears to be easily disseminated from shallow or broad receptacles. It is a cheap method, as at the present price of carbon tetrachloride the expense of delousing the entire outfit of a soldier would be about 5 cents per man. The tests were made at temperatures ranging from 68° to 72° F. It is to be inferred that the results would not be so good at lower temperatures and Foster suggests that further work along this line is desirable. However, the temperatures prevailing at the time the tests were performed were approximately those of artificially warmed living habitations even in winter. Certain experiments made to determine the power of carbon tetrachloride vapor to kill the ova of the body louse have not been completed. It was definitely determined though, that the nits are not killed by treatment with 30.5 c.c. of carbon tetrachloride to the cubic foot of space, with two hours' exposure. Foster draws attention to the fact that carbon tetrachloride is somewhat more poisonous than chloroform and this must be considered when dealing with its applicability as a delousing agent.

Slain in the War.—The British War Office has announced to the House of Commons that the British losses on all fronts during the war were 667,665. Of these, 37,836 were officers and 629,829 were men. The British wounded totaled 2,932,122, while the missing, including prisoners, were 359,145. The total casualties were 3,949,991. A despatch from Copenhagen states that the *Vorwärts* of Berlin says it learns on reliable authority that up to October 31 1,580,000 German soldiers were killed, and 4,000,000 wounded, some several times. There are said to be 490,000 German prisoners in other countries. The American casualties in the war number 236,117. There were 36,154 killed or died of wounds; 14,811 died from disease, and 2,204 deaths are unclassified.

The wounded number 179,625, prisoners 2,163 and missing 1,160.

War Department Stops Hospital Construction.—Among the construction projects recently cancelled by the War Department was a contract for a large hospital at Fort Omaha, Nebraska.

Work of City Club's Ambulance Unit.—The ambulance unit sent abroad by the City Club of New York has transported more than 50,000 wounded men from the front lines to dressing stations and hospitals in France. Fourteen of the drivers serving with the unit have been decorated with the French War Cross; and, in addition, as a result of the club's war activities, funds have been supplied for the support of 1,600 fatherless children of France.

Wounded Soldiers Arriving.—A transport from France landed 426 wounded and convalescent soldiers and 24 officers at Hoboken on November 23, all of whom were transferred by Red Cross ambulances to the New Army Hospital at Eighteenth Street and Sixth Avenue, formerly the Greenhut Building. These were the first patients received by this hospital, which opened for their reception with a staff of 400 enlisted men, 45 physicians, and some 70 regular army nurses, headed by Major W. J. Monaghan. This hospital is prepared to care for 4,000 men.

Red Cross Announces New Enrollment.—The American Red Cross will hold a Christmas roll call during the week of December 16 to 23. During this week every chapter in the country will conduct a campaign to reenlist all the present members and to enroll new ones at the annual fee of one dollar.

Maj.-Gen. William C. Gorgas will soon, it is announced, resume his work for the eradication of yellow fever in South American countries that he abandoned temporarily when the United States entered the world war. He will leave shortly for Central and South America, having been preceded to Guayaquil, Ecuador, by Dr. M. E. Connor, who will assist him in putting into effect the program of the International Health Board of the Rockefeller Foundation. In a recent statement, Dr. Vincent, president of the Rockefeller Foundation, pointed out that the survey of the situation by the Rockefeller experts had led to the opinion that the total eradication of yellow fever was feasible through the extermination of the stegomyia mosquito.

Deaths in the Service.—Captain Frank Henry Knight, M.C., U. S. Army, of Brooklyn, N. Y., attached to Base Hospital No. 23, at Portsmouth, England, died there of pneumonia on October 28, aged 42 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1899, a member of the American Medical Association, and a Fellow of the American College of Surgeons. Prior to his entrance into the service, Dr. Knight was chief gynecologist at the Methodist Episcopal and Swedish Hospitals, assistant visiting surgeon to the Kings County and St. John's Hospitals, and visiting surgeon to the Episcopal Orphan Asylum and the Home for the Aged.

Lieutenant August Adrian Strasser, M. C., U. S. Army, of Arlington, N. J., died of paralysis in Newark on November 19, aged 44 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1896, and a former president of the New Jersey Academy of Medicine. He was until recently stationed at Fort Oglethorpe, Georgia.

Lieutenant-Colonel Alexander Watson Williams, M. C., U. S. Army, a graduate of Johns Hopkins University, Baltimore, in 1912, an honor graduate and medalist of the Army Medical School in 1913, died from illness, in France, on October 5, aged 34 years. Colonel Williams served in Manila from March, 1916, to November, 1917, and on his return to the United States organized and equipped for overseas service Hospital Train No. 29, at Fort Benjamin Harrison, Ind., and was on duty at Camp Sherman and Camp Lee before he went to France.

Assistant-Surgeon William Henry Buffum, Lieutenant, U. S. Navy, of Providence, R. I., died in a hospital in Liverpool, England, on October 13, from pneumonia, aged 41 years. He was a graduate of Harvard University Medical School in 1902 and one of the officers of the Rhode Island Naval Hospital Unit which started overseas a few weeks ago.

Captain Alfred Glascock, M. C., U. S. Army, of Washington, D. C., died from pneumonia on October 10 in France, where he was serving as psychiatrist at a base hospital. He was a graduate of George Washington University, Washington, D. C., in 1902, and formerly a member of the staff of St. Elizabeth's Hospital, Washington. He was 37 years of age.

Lieutenant Thomas Purley Johnston, M. C., U. S. Army, of Mount Gilead, Ohio, a graduate of the Ohio State University, Columbus, in 1910, died from pneumonia in an American Base Hospital in France, on October 7, aged 36 years.

Captain Claude Melville Campbell, M. C., U. S. Army, of Decorah, Iowa, a graduate of the North Western University Medical School, Chicago, in 1910, on duty at Fort Riley, Kan., died at Glencoe, Minn., October 23, from pneumonia following influenza, aged 33 years.

Lieutenant Grover Carter, M. C., U. S. Army, of Memphis, Tenn., a graduate of the University of Tennessee, Nashville, in 1917, was killed by a shell, on October 16, while attending a wounded officer. He went overseas in October, 1917, serving first at a base hospital in England and later assigned to duty with the British Army in Flanders, and attached to the One Hundred and Twenty-First Brigade, Royal Flanders Artillery.

Lieutenant Winfield Scott Faulds, M. C., U. S. Army, of Roy, Montana, a graduate of Dearborn Medical College, Chicago, in 1906, commanding Camp Hospital No. 7, Thirty-Third Division, in France, died recently of pneumonia, at the age of 45 years.

Lieutenant Burton Robert Carpenter, M. C., U. S. Army, of Clifton, Texas, a graduate of the Fort Worth, Texas, School of Medicine, in 1912, ordered for duty at Fort Riley, Kans., died from pneumonia at Clifton, on October 28, aged 29 years.

Lieutenant Louis Robert Kratze, M. C., U. S. Army, of Chicago, a graduate of the University of Chicago in 1912, died recently from influenza at Camp Crane, Allentown, Pa., aged 35 years.

Lieutenant Franklin Marshall Hawley, M. C., U. S. Army, of Bayfield, Wis., a graduate of Drake University, Des Moines, Iowa, in 1883, died from spinal meningitis while on duty in a hospital in France on October 2, aged 55 years.

New York, November 30, 1918.

THE SYMPTOMATOLOGY OF NEOPLASMS OF VATER'S AMPULLA.

THE commencement of a neoplastic process in the ampulla of Vater differs from one case to another, but in a general way there are premonitory phenomena of dyspepsia, pain, or symptoms of a general nature. In some instances the appetite may be increased, while in others it is diminished and in the latter circumstance distaste for meat is common. Digestion may become slow, with a sensation of epigastric fullness after eating. Occasionally, but less frequently severe paroxysms of pain with vomiting take place. Alternatives of diarrhea and constipation may arise. If, regardless of normal alimentation, marked emaciation occurs along with these digestive symptoms a neoplasm will naturally be suspected although its site remains obscure. The appearance of icterus, which is the important symptom, and opens the scene in about 50 per cent. of the cases, will draw the practitioner's attention to the biliary tract.

Icterus is a constant and valuable symptom. It may occur suddenly in an otherwise healthy person, while in other cases its appearance is preceded by a general malaise or even digestive disturbances with colic. It is a slowly progressive icterus which finally culminates in melanodermic jaundice. It should be remarked that, in the early stage, the icterus may be intermittent, a fact insisted upon by Hanot, Rendu, and other observers. Hanot explains this phenomenon by a spasmodic contraction of the orifice of the choledochus, while Rendu considers that the cause resides in the variability of the vascularization of the neoplasms from which arises their turgescence at certain times, resulting in the occlusion of the choledochus. Stokes suspects that the growth may act as a valve in some cases. The icterus has the characters of a retention jaundice, that is to say, that the feces are decolorized and the urine very deeply stained at the same time. The decolorization of the feces may undergo certain variations, a fact explained by the permeability of the choledochus at the level of the ampulla. The urine is loaded with bile pigment and both Gmelin's and Grimbert's reactions are positive. Glycosuria has been met with in only one case.

Pruritus is very common and so severe that it alone may necessitate operative interference for the patient's relief. Xanthelasma has been noted occasionally. The digestive disturbances are vague. At one time it was thought that diarrhea was an important diagnostic element but it is absent in about 50 per cent. of the cases, so that its value is not great. Microscopical examination of the feces shows large numbers of fat drops after the ingestion of fat. The fats are not split up, owing to the absence of the pancreatic fluid, hence diarrhea. If the patient be given potassium iodide enveloped in gelatin, the envelop is not dissolved so that no iodine will be found in the urine. Search for elastic and muscle fibres after a meal of meat reveals their presence in the stools. The ingestion of salol is not followed by the elimination of salicylic acid in the urine. Intestinal hemorrhage in the form of melena is rare. Occult hemorrhage, to which Boas has called attention, is certainly not frequent.

Among the subjective signs pain has little diagnostic value. It is often absent and when it does exist, it is not intense. It occurs before or at the time that icterus appears. Fever was noted by Courvoisier in 25 per cent. of cases of biliary lithiasis and in 10 per cent. of cases of neoplasms of the biliary tract. Cerebral disturbances may supervene toward the end of the process with or without delirium, or coma with convulsions may end the drama. Blood analysis shows a great decrease of hemoglobin, even as much as 50 per cent., while the red blood corpuscles are greatly reduced.

To complete the clinical picture a word should be said concerning the local examination of the biliary tract. Exploration of the tumor is often difficult but an attentive examination will show that the liver is enlarged, smooth, and hard. In the region of the gall-bladder a mobile, resistant, and painful mass can be made out, the gall-bladder being, according to Courvoisier, increased in size in 92 per cent. of the cases. Retention icterus, with decolorization of the feces and dilatation of the gall-bladder constitute the Courvoisier-Terrier syndrome, which is opposed to the lithiasis syndrome with intermittent icterus and retraction of the gall-bladder. The former syndrome is of the highest value in the diagnosis of neoplasms of Vater's ampulla and in its absence a diagnosis becomes impossible.

THE POLYCYSTIC KIDNEY IN THE ADULT.

THE evolution of the polycystic kidney in the adult is far from being uniform and the duration of the morbid process varies in considerable proportions. It is a matter of some difficulty to estimate the limits of the evolution because some cases progress with astonishing rapidity, the patient dying in his first attack of uremia, before which he had offered no symptom, while nevertheless necropsy revealed very large polycystic kidneys. In other instances the evolution is less rapid and from the time the initial symptoms are observed the patient may live for two or three years and frequently more than a decade.

The commencement of the process is likewise extremely variable, the first symptomatic phenomenon being either the clinical evidence of nephritis, neoplasm, pain, or hematuria. Uremia is the most common cause of death, being observed in one hundred and twenty clinical histories collected by Zelniker (Thesis, Paris, 1915).

Albarran and Imbert have described three clinical forms of this morbid process, the first being the uremic, characterized by the sudden development of uremic accidents in an apparently healthy subject. Death usually takes place in eight or ten days. The Brightic form is slow in evolution and offers the classic picture of chronic nephritis, ending more or less rapidly in uremia. The renal form is characterized by evident renal symptoms such as abdominal or lumbar pain and hematuria.

This last form was looked upon by Pousson as the surgical type of the process, under the misnomer of polycystic kidney. He opposes to the true polycystic kidney—a bilateral affection of unknown etiology—the pseudo-polycystic kidney which has a nephritic, lithiasic, hydronephritic, or tuberculous origin and which is often unilateral.

On examination, the unilaterality of the process does not appear to be more frequent than in essential cystic degeneration, since out of a total of twelve autopsies the lesions were bilateral in eleven. If the symptomatology be considered, it will be found to differ little from that of true polycystic kidneys. Tumor, pain, hematuria, and symptoms of chronic nephritis are encountered and to these symptoms of lithiasis are added and radiography will reveal renal calculi. The complexity and variability of the symptoms of polycystic kidneys explain why the diagnosis is often wrong, but in all cases in which it has been made, a bilateral renal tumor could be felt. Ureteral catheterism and radiography will greatly help.

Renal lithiasis, which may coincide with polycystic degeneration, can be eliminated by the *x*-ray and ureteral catheterism will settle the diagnosis when bilateral enlarged kidneys are the result of tuberculosis. In renal cancer the kidney may be greatly enlarged and give rise to hematuria or the urine may be absolutely normal. Hydronephrosis is diagnosed by the ureteral catheter.

Generally speaking, no surgical interference is required during the progress of a polycystic kidney undergoing a normal evolution, and an early diagnosis is essential in order not to interfere. The only surgical interference will be that for complications such as suppuration, hematuria, and anuria. Before resorting to operation the functional activity of both kidneys must be ascertained and if found insufficient on the supposedly normal side, nephrectomy is contraindicated. If, on the contrary, the opposite kidney is judged functionally sufficient, nephrectomy is indicated in cases of suppuration of the cysts, while in anuria nephrotomy is the only proper operation. In the uremic and, therefore, nephritic form, the only proper therapeutic measures are those of interstitial nephritis.

WARBURG'S TINCTURE IN THE TREATMENT OF INFLUENZA.

THE treatment of influenza naturally has given rise to a good deal of discussion during the past few weeks. It is perhaps a question if drugs other than alkalies are needed to any great extent in a mild attack of influenza, rest and careful nursing being possibly the most important factors making for recovery. But in severe cases the fever and other evidences of profound intoxication call for medicinal therapy—the salicylates, one of the synthetic antipyretics, or quinine. Regarding the latter, Warburg's tincture has long held a reputation in tropical countries as a remedy of undoubted and indeed unequalled power in the treatment of malignant malarial fevers and cholera. Testimony to this effect is unassailable. Now the chief component of this preparation is quinine, each ounce containing nine and a half to ten grains of the alkaloid. One might, therefore, be inclined to say, and some have said, that the main if not the only virtue of Warburg's tincture lies in its quinine content. But many of those who have had experience in treating the remittent fevers contracted in the jungles and swamps of the tropics have stated definitely that quinine when given alone does not exert the beneficial effect of the tincture. Professor McLean, writing in the *Medical Times and Gazette* so long ago as 1875, said that he had never seen a single dose of quinine given alone, to the extent of nine grains and a half, suffice to arrest an exacerbation of remittent fever or prevent its recurrence, while nothing is more common than to see the same quantity of the alkaloid in Warburg's tincture bring about these results.

The late Sir William Broadbent was enthusiastic regarding the therapeutic merits of Warburg's tincture, and, moreover, analyzed and explained in *The Practitioner*, February, 1877, why the preparation was superior to quinine by itself. The great principle of its action is the combination of quinine with powerful aromatics. It is likewise aperient from the aloes, rhubarb, etc., contained in it, and this may also contribute to its usefulness. Again, a large dose of quinine sometimes not only gives rise to the usual symptoms of cinchonism, but produces a good deal of prostration. This result may be counteracted by aromatic stimulants. In the opinion of Broadbent there is a second therapeutic principle involved in the employment of Warburg's tincture, namely, concentration. And it must be pointed out that there is a therapeutic administration of drugs to which physiological experiment affords no clue, and for which the condition of the patient is the indication. The effects are largely due, according to Broadbent, to the powerful impression made in consequence of this concentration upon the nervous system. The instructions given for the use of Warburg's tincture are that the bowels shall have been freely open, that no food

shall have been given recently, and that two doses shall be administered without dilution at an interval of two or three hours. The remedy thus enters the empty stomach in a highly concentrated state, and is no doubt rapidly absorbed. If Warburg's tincture does produce the remarkable effects in remittent fevers and in other acute infections, which it is stated to produce, why might it not be used in place of pure quinine or of the coal tar drugs in the treatment of influenza? It matters little if its action cannot be clearly explained from the physiological standpoint, for we have not yet wholly emerged from the empirical stage in therapeutics, if we ever shall.

AEROPHAGY.

AFTER aerophagy had been distinguished in the clinic from flatulent dyspepsia a large literature came into existence with many refinements in classification. It was grouped by causes, location, symptoms, syndromes. When fluoroscopy was introduced an objective study corroborated the earlier finds. Air could be seen to collect in the stomach and cause pressure and reflex symptoms which vanished when the air was expelled. Despite all its varieties of expression aerophagy is the most simple of affections *per se* although associated with the most varied conditions. An air swallower is always a dyspeptic, always suffers from gastric atony or hyperesthesia, is always neuropathic. The act of swallowing saliva (sialophagia) which plays so important a role in aerophagy may amount to a habit spasm, a form of obsession, and is always associated with hyperchlorhydria.

The foregoing represents the conception of aerophagy by Lyon, who regards the treatment of the affection as relatively simple. The dyspepsia is usually of a mild, benign type and the atony, whether this is a primary or secondary manifestation, yields to a combination of massage, gymnastics and hydrotherapy. One should lie recumbent for a long time after meals and should wear a swaddling band if the screen shows a state of gastric elongation. The diet should be balanced, the food taken dry and well chewed. Hot drinks long after meals are advised. About the only drugs indicated are sodium salts in the form of carbonate, chloride, phosphate, and sulphate (the author suggests a number of combinations). Exceptionally sedatives may be necessary—belladonna, codeine, valerianates, bromides, chloroform water. Lyon would probably begin treatment with vibratory massage, hot local hydrotherapy, a bromide enema at night, meals taken recumbent, perhaps followed by belladonna or chloroform water. Marked hyperchlorhydria, suggesting ulcer, would call for other measures.

Diagnosis in the Influenza Pandemic.

DUBOIS in the *Archives Médicales Belges* for September contributes a review of this subject from many sources, from which we extract certain points of general interest. The various accounts by different writers from many different countries by no means are superposable over one another. Common to all are the brusque début, the throat pains which serve to exclude ordinary feverish colds, with a peculiar retrosternal pain, the notable prostration, the anorexia, the burdensome convalescence, etc. Contagiosity is marked, with incubation brief. There are very many abortive or, if one prefer, mild cases. If we consider the subject globally, diagnosis has lain chiefly between three affections—ordinary influenza, pappataci fever, and a new malady. In regard to pappataci fever, this has been considered a possibility only in those localities where the latter flourishes. The affection, however, is one and the same in all countries, and the presence of the usual complications of pandemic influenza in Italy, such as bronchopneumonia, should exclude the pappataci theory. The latter disease is noted for its monomorphism, as distinguished from the polymorphism of influenza. Especially is the pappataci fever free from pulmonary complications, a result perhaps due in part to its summer incidence. Our association of influenza with cold weather is evidently largely fortuitous. But a question arises which has not yet been answered—may virulent influenza be transmitted by insects? We recall in this connection that the question was asked by certain Spanish writers, although the majority scouted the idea. In some Italian episodes men on shipboard were infected under such circumstances that only an insect borne infection seemed rational. Such a possibility would constitute a connecting link between these diseases, but while in pappataci fever it is the chief or sole method of communication, in influenza it must be a very unusual one in comparison with mouth to mouth infection.

Myocarditis from Mumps.

FROM an abstract in the columns of the *Journal de médecine et de chirurgie pratiques* for October 10, we learn that Pujol, who is in charge of a cardiological center, has been seeing cases of this rare complication or sequel of parotitis. In Hudelo's monograph on mumps the existence of such a complication is denied outright; hence cases which do develop are presumably latent. During the war many things have been learned of this disease (mumps) in adults and among complications and sequelæ newly listed are the following: prolonged asthenia, meningitis, nephritis, pseudorheumatism of infectious character, all of which are fairly common. Pujol has seen 12 cases of myocarditis in 450 cases of mumps in soldiers. The complication appears under different guises. It may announce itself spontaneously by symptoms pointing directly to the heart, but in the majority it does not become evident until the heart is subjected to a sudden unwonted strain. For example the patient mounts a ladder and at once becomes dyspneic. Again, while marching he falls behind his comrades. But examination of the heart, the patient being in repose, reveals nothing wrong. If now he is subjected to tests for efficiency under strain the shortcomings of the organ are manifest. The usual tests are some

form of mild exertion maintained for a full minute, after which tachycardia will be apparent requiring at least four minutes to regain equilibrium. The ultimate prognosis is probably good, but the subject will have to change his calling if the latter is active to a less violent one. Thus a farmer will have to limit himself to work of a light class, after his release; a farrier will have to give up his calling altogether, etc.

Public Health in Cuba.

Sumptuous reports are issued monthly (in Spanish, French and English text) entitled *Sanidad y Beneficiencia*, which cover the sanitary and hygienic activities of Cuba; and from the May-June number we extract the following information. Four pestilential diseases—lepra, tuberculosis, rabies, and typhoid—are considered from the viewpoint either of prevention or cure. The adverse report on the Garcia plan for the treatment of leprosy has already been mentioned in the columns of the Medical Record. Contributions on Cuban tuberculosis deal only with isolated aspects of the malady, as there is no general crusade in progress at the present time. The results of antityphoid inoculation as tried out in certain districts appear to be very encouraging. The report on rabies will be of the greatest interest to the United States citizen, for it is not generally known that a Pasteur institute for the prevention of rabies was established in Cuba as far back as 1887. Last year, therefore, a report covering thirty years' activities could be analyzed. During this period 5,188 individuals received the preventive treatment. The number of bitten people who nevertheless developed rabies was 36, a percentage of failure of 0.065. From 1900 to 1909 there was a notable falling off in the number requiring inoculation; but at that juncture this number jumped from 19 to 465. From 1898 to 1908 there was not a single death recorded from the disease, but since the latter year 15 deaths have occurred from this cause. The report does not give any reason for this falling off and subsequent rise. It is known that since the statistics went into effect, 77 deaths from hydrophobia have occurred in unvaccinated subjects.

The "Hole in the Hand" Experiment and Binocular Vision.

In parlor physics an illusion is sometimes demonstrated as follows: A sheet of newspaper is rolled up to make a tube three feet long which is held in the right hand in front of the right eye which is focused through the tube upon some distant object. The left eye is directed upon the palm of the left hand which is held by its ulnar side against the tube and near its peripheral end. The two eye pictures are fused in the brain so that the right eye appears to see its objective through a hole in the left hand. Dr. Cantonnet, a French oculist, was apparently the first to introduce this experiment into ophthalmology and in a recent monograph by Remy on the diploscope receives credit for the same. While this instrument is indispensable to the specialist the general practitioner by the use of Cantonnet's test can obtain satisfactory evidence of binocular vision. Cantonnet says that the hole in the hand test possesses therapeutic virtues as well in diplopia, but he does not insist upon this, since treatment of this condition is reserved for the ophthalmologist. If the hole is seen in the middle of the hand binocular vision is perfect. If seen on the right side there is exaggerated convergence; if on the left side divergence. There may also be a vertical deviation.

News of the Week.

Jerusalem Freed of Mosquito Plague.—The Zionist Organization of America, through the efforts of Louis Cantor of Rochester, N. Y., who is a member of the American Zionist Medical Unit, has freed Jerusalem of the mosquito pest. It is said that the city is now practically free of these carriers of malaria. During Mr. Cantor's campaign 350 cisterns were petrolized and put in sanitary condition. Mr. Cantor was formerly connected with the Goethals Commission at the Panama Canal.

Optical Industry Must Conserve.—There is a world wide shortage in spectacle lenses, frames and mountings, in consequence of which the War Service Committee of the Optical Industry announces that the conservation policy adopted by the trade for the war will be continued during the reconstruction period. All manufacturers have discarded the dozen system and will sell in the future by the decimal system.

Dr. William G. Bissell of Buffalo has been chosen president of the New York State Board of Medical Examiners.

Dr. John A. Moore of Westport, Conn., has been appointed health officer of Weston, Conn.

Dr. Samuel B. Woodward has been chosen president of the Worcester (Mass.) Society for the Prevention of Cruelty to Children.

Dr. Earl J. Mathewson has been elected City Physician of Pawtucket, R. I., to fill the unexpired term of the late Dr. Walter A. Watts.

Dr. Beverley Robinson of New York has been elected corresponding member of the Société Médicale des Hôpitaux of Paris. Dr. Robinson is an ex-interne of the Paris hospitals.

Court Restores Doctor's License.—The decision of the courts of San Francisco has restored Dr. Marion Thrasher's license to practise medicine, which was revoked some months ago by the State Board of Medical Examiners for alleged unprofessional conduct.

Dr. Charles E. Donlan has been reinstated as superintendent of the Long Island Hospital of East Boston, Mass.

The American Public Health Association will hold its annual meeting in Chicago, December 9 to 12. The headquarters will be at Hotel Morrison. Inquiries may be addressed to the secretary at 989 Boylston Street, Boston, Mass. The program is designed to bring out all available information concerning the management of epidemic influenza, though other aspects of public health will not be neglected. Among the papers to be read are the following: "Etiology of Influenza," by Major William H. Welch; "Mobilization of Medical and Nursing Forces," by Assistant Surgeon General J. W. Schereschewsky; "Influenza and Pneumonia Vaccines," by Dr. E. C. Rosenow;

"The Use of Sera in Influenza," by Drs. McGuire and Redden; "The Face Mask," by Colonel Charles Lynch and Dr. George Weaver; "Organization of State and Federal Forces in Epidemics," by Assistant Surgeon General A. W. McLaughlin and Dr. E. R. Kelley; "History and Statistics of the Epidemic," by Assistant Surgeon General B. S. Warren.

Obituary Notes.—Dr. THOMAS H. WERICH, a graduate of the University of Michigan College of Medicine in 1873, died of pneumonia at his home in Wellsburg, W. Va., on November 6, aged 73 years.

Dr. HINTON G. FUSSELL, a graduate of the Atlanta (Ga.) School of Medicine in 1912, died at his home in Camilla, Ga., on October 29, aged 29 years.

Dr. ANTONIO RUBINO of Paterson, N. J., a graduate of the Royal University of Modena, Italy, in 1910, died in a local hospital from illness brought on by overwork during the influenza epidemic, on November 22.

Dr. JOHN S. MELTZER, a graduate of the University and Bellevue Hospital Medical College in 1912, died of pneumonia at his home in New York City on November 16, aged 31 years.

Dr. CHARLES EMORY PAINE, a graduate of the New York Homeopathic Medical College in 1903, died at his home in Brooklyn on November 18, aged 31 years. He was a consulting physician to the Jamaica and Cumberland Street Hospitals and on the advisory board of the Peck Memorial Hospital. He was a member of the New York Homeopathic Society and the Pathological Society.

Dr. EDWARD D. PECK of Caldwell, N. J., died of apoplexy on November 22, at the age of 64 years. He had been to see a patient, and was stricken in the garage on his return. He was a graduate of the Bellevue Hospital Medical College, New York, in the class of 1879. Dr. Peck was mayor of Caldwell, and had recently been reelected to a second term without opposition.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

INFLUENZA IN LONDON—DEATH OF MR. R. BRUDENELL CARTER—COMMISSION ON PUBLIC HEALTH IN EGYPT—ADDITIONAL FUEL IN CASES OF CHILDBIRTH.

LONDON, October 30, 1918.

THE influenza epidemic reached what is presumed by those experienced in urban epidemiology to be its height, in the closing week of October; and the last week of the month, though the incidence of cases was larger found the mortality rate lower. There were 1250 deaths in London in the week ending October 26. A declining mortality is not in accordance with the views that have been expressed by some authorities upon the probable behavior of influenza, for the epidemic has in many instances been noted to grow severer in type even while it is growing lighter in numbers. The members of the medical profession in London and the suburbs have been sorely tried by the outburst, and the time of strain remains while I write. Doctors have been working night and day in the endeavor to attend adequately to their patients, and the circumstances of the fourth year of the war have not made their task any lighter. Undoubtedly a large proportion of the population who have suffered from influenza have been over-worked owing to the shortage of man power, and over-anxious owing to the harrassing conditions of domestic life under rationing systems. Absence of light and difficulties in traveling by motor car, train, or omnibus, have also aggravated the difficulties of doctors and the anxieties of patients. On the other hand, the high wages enjoyed by the greater part of the industrial and operative classes, regardless to some extent of sex or age, have made it possible for most families to obtain the special nutriment required in spite of prices and scarcity. The mortality would certainly have been far greater had not the population possessed the means to secure the necessary warmth and nutriment and had not rationing schedules been found unexpectedly elastic.

The urgency of the situation has been realized in official ways. Sir Auckland Geddes, the Minister of National Service, and himself a medical man, has issued an official order cancelling the calling-up notices for medical examination of recruits. The meaning of this is that for the time being all the medical officers who were engaged upon the anxious and difficult work of inspecting, passing or rejecting recruits are set free from the recruiting boards. Where these doctors have private practices they have already returned to them, and where they have not been in practice, their services have been requisitioned for the country's need, and they have been drafted to localities where their services were particularly required. There is for the time being no lull in the demand for medical men with the Navy and Army as was hoped. There is full work for medical men to do in both services. For the immediate present, health at home is held to be the first consideration, so long as the wounded men in the active zones are duly cared for, so that the Recruiting Boards have been depleted. The lay newspapers have been abounding with regulations which should be observed by the public in regard to the epidemic, and for the most part these regulations have been of no value whatever to the population. Nothing recommended by the newspapers has been additional to the routine medical advice widely disseminated by the medical profession, nor have any of these lucubrations added anything whatever to the general counsels laid down by Sir Arthur Newsholme, Principal Medical Officer to the Local Government Board. The daily newspapers have in fact been a source of considerable danger to the community by magnifying the risks of the disease and thereby in the opinion of many people increasing the susceptibility of the population. For example, Mr. E. W. Morris, House Governor of the London Hospital, has circulated for the advice of the populations in the East End of the metropolis, where his hospital is situated, a leaflet containing simple and admirable rules to be observed in regard to the epidemic. Among the rules is the following: "Do not talk about influenza. It is wearing itself out and will go all the sooner if you do not talk about it. Influenza is a disease

that likes to be noticed." This advice is extremely sound, and to publish a leaflet containing it need not defeat the advice, if the advised persons do not talk. This is an obvious point which apparently has been missed by the daily papers, who have selected that particular one of Mr. Morris's rules for disquisition and advertisement. It is of course a disquieting fact for the public as well as for the medical profession that the nature of the epidemic should be confessedly mysterious. Some authorities think that it is conforming to the ordinary pattern of influenza, notably to the pattern which prevailed 28 years ago all over England. Others find it an entirely new disease, quoting in particular the fulminating nature of the attacks and the frequent occurrence of hyperpyrexia. The pathology is obviously complicated, three separate germs being recognizable. Lastly, there is an absolute difference of opinion as to whether associated symptoms of encephalitis or of poliomyelitis are part of an influenza syndrome or are intercurrent attacks in debilitated subjects of separate diseases. There is no doubt about it that the pathology of influenza requires still a great deal of investigation.

The death has just occurred in his 90th year of Mr. Brudenell Carter, consulting ophthalmic surgeon to St. George's Hospital, an ex-president of the Medical Society of London, and for 50 years a leading writer in the columns of the *Lancet* and the *Times*. A good linguist, and a beautifully clear and learned writer, he brought his gift into full play also as an orator, and for twenty years, as representative of the London Society of Apothecaries, he was an influential member of the General Medical Council. He wrote an admirable text-book of diseases of the eye, which, however, was not kept up to date and is now superseded by more recent manuals; he also furnished the ophthalmological sections to the two great "Systems of Medicine" in the seventies, namely, "Holmes's System of Surgery" and "Quain's Dictionary of Medicine."

In June, 1917, Sir Reginald Wingate the Egyptian High Commissioner took the prescient step of appointing an official inquiry into the future organization and work of the Public Health Department of Egypt. It was not however until June of this year that preliminary arrangements were completed, and the Commission was duly appointed, with the following constitution: President, Lieut.-Col. Andrew Balfour, lately Director of the Welcome Research Laboratories; members, Lieut.-Col. G. E. F. Stammers, Mr. E. S. Crispin and Dr. Charles Todd. Mr. Crispin is the Director of the Medical Department of the London Government, and Dr. Todd is the Director of Laboratories to the Egyptian Public Health Department. I refer a little at length to the Balfour report in a London letter because the disposition of reforms in accordance with its recommendations will certainly call for central influence, and will not depend alone upon Egyptian activities.

The Commission on getting to work instituted a series of inspections in Cairo, Alexandria, and the provinces, thus familiarizing themselves with the different aspects of the work controlled by the Public Health Department of Egypt. It met on 76 occasions and the result is the return to the Egyptian Prime Minister of a very outspoken series of findings. The report begins by recording an impression that the general scheme was devised by the Public Health Department in Egypt for dealing with the many and difficult health problems of Egypt—such as checking the spread of cholera, plague, typhus, and relapsing fever. In those important respects the Commission found that the future needs of the country had received great attention, while from the general health point of view much foresight had been exercised and well directed labor expended. The report singles out for special and favorable mention the worth of the late assistant director of the Department Dr. Cyril Goodman, whose experience was obviously of great value to the Commission in many directions. But the Egyptian Public Health Department suffers from having no proper official status, being not an entity but merely a branch of the Ministry of the Interior; it has therefore no direct official access to the High Commissioner, and all the recommendations run the usual risk of being blocked by stress of other business.

Upon the outbreak of war the efficiency of the Public Health Department was unduly affected. says the Report, by the fact that its officials were allowed to be seconded for duty with the troops at the very moment that the personnel of the Department should have been strengthened instead of weakened. Effective organization managed to avert any disaster, but the unnecessary trouble that was caused in this country by a too precipitate utilization of all available military assistance, was coincident in Egypt. The Report outlines the present day conditions in Egypt so far as they have a bearing on Public Health work, is hopeful concerning the effect of education in modifying the outlook of the Egyptian now, while rendering the future of sanitation more hopeful. "It is obvious," says the Report, "that the signs are propitious and though owing to the war the time may not yet be actually ripe for extensive modifications in health organization, yet it is clear that the present period of change and advance offers special facilities for the consideration of a scheme of reform." After such hopeful words the Commissioners speak in almost unmeasured language of the plague of filth in Egypt and the first or general section of the Report concludes by unanimous agreement that a Ministry of Health is essential for securing proper sanitary reform in Egypt. The time has gone by, the Commissioners think, when the public health of this vast and developing country, with numerous gradual and particular sanitary problems to face, can be rendered and kept healthy by the work of a sub-bureau.

The scheme for a central health organization follows, and commences with the statement that the Ministry of Health must be a separate bureau and that the directing head should be an Under Secretary of State. Immediately below him it is suggested there should be a Director General of Health, who is intended to be the main driving force in the Ministry, as his duties will require

him to coordinate the work of important subordinates having specialized functions as well as to prepare the Annual Budget. The President of the Ministry will also have the advantages of a Technical Advisor who, under the alternative title of Director of Medical Intelligence, will conduct a bureau of information, keep himself in touch with scientific developments in other countries, and control, also, an educational museum. The President will preside over a Central Board of Health which, it is suggested, will be completed by 7 officers appointed as directors of Sanitary, Epidemic and Medical Services, Lunacy, Medical Education, Public Health Laboratories, and Sanitary Engineering. A Secretary General will be added not only to keep the records, but to deal with all questions relating to subordinate personnel, and to sift the work of the Director General who might otherwise become overburdened with details.

Passing into the consideration of the provincial organization of public health in Egypt the Commission finds that this has been less satisfactory than the central administration, owing to the paucity of inspectors. The Commission think that a good type of such man would be an officer of the Royal Army Medical Corps because of his special training in hygiene and appreciation of discipline. They add that the post should be filled by a man of about 25 years of age, but in that case his experience as an officer of the R. A. M. C. would necessarily have been of the shortest. The further details concerning provincial medical administration are very interesting, as showing how thoroughly and conscientiously the Commission interpreted their mandate, but the essential question of the moment is—will the Ministry of Health for Egypt be established? Now is the psychological time for such a reform in Egypt as in England; but in England the new legislation still tarries, owing presumably to lack of time on the part of those who would bear the burden of reconstruction. Alas, there is reason to suppose that the same difficulty exists, perhaps in exaggerated form, among those in charge of Egyptian affairs.

With obvious wisdom Sir Guy Calthrop, the Controller of Coal Mines, has admitted the validity of claims for an additional fuel allowance in respect of cases of child-birth. The maximum quantity of additional fuel granted in response to such claims will be 5 tons, a liberal allowance in face of the known fact that a speedy peace cannot be followed by a speedy relief in the coal situation.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

DISCUSSION ON INFLUENZA AT THE ACADEMY OF MEDICINE—SAVING PARIS BABIES—TEACHING THE SOLDIERS TO BOX.

PARIS, October 21, 1918.

DR. NETTAR, in a new communication to the Academy, pronounces the present form of malignant grippe which has made its appearance in several parts of Europe, as identical with the epidemic of 1889-90. He recognizes the characters of the two epidemics as the same: capillary bronchitis, bronchopneumonia, massive pneumonia, purulent pleurisy, general asthenia, serious invasion of the nerve centers, and in some instances serious heart complications. M. Nettar attributes the cause to the coccobacilli of Pfeiffer which are found in the products of the expectoration and frequently in blood cultures; these bacilli are generally associated with pneumococci and streptococci, which were found in the influenza of 1889. There is no similarity with the so-called three-day fever of the Orient, which is caused by the bite of a variety of very small gnat, and subjects suffering with grippe never complain of insect bites. The epidemic of 1889 had its origin in Russia, and went by the name of Russian influenza, and there was no justification for the term Spanish grippe for the present invasion, it being a recurrence of the first-named complaint.

The communication gave rise to a lively debate. Drs. Wurtz and Besançon made a report upon their observations of cases which by reason of their sudden and brutal onset caused them in some instances to be mistaken for cholera; at the death of these the surface became violet, almost even black. They regard the cases of severe dysentery which were numerous in Paris in the summer as a variety of the same causative agents.

Dr. Patein called attention to the enormous dosage of urea found in the urine of some of the cases which largely explained the state of asthenia that presented, and he considered these conditions as indicating a regime of nourishment by milk during the severe part of the attack.

Dr. Ravaut stated that in the region of Marseilles many cases were early seized with difficulty of breathing, asphyxia and edema of the lungs. He proposed as treatment for these cases first phlebotomy, withdrawing from 500 to 700 grammes of blood, giving at the same time hexamethylenamine as a diuretic.

Dr. Raphael Dubois stated he had achieved success in his cases by administering a teaspoonful of powdered yellow calasaya bark three or four times per day in black coffee.

Dr. E. Roux, director of the Pasteur Institute, presented a report made by Mlle. Chaptal regarding the assistance to mothers and infants made by the Department of Health in the fourteenth arrondissement. In 1901 this arrondissement possessed a population of 79,000 and no help of the character described was rendered. The infantile mortality surpassed 20 per cent. Mlle. Chaptal attributed this high mortality chiefly to the fact that babies were not nursed by their mothers, and her first work was directed to the instruction of mothers in the importance of this; she instituted lectures upon hygiene and alimentation, and gave gratuitously orders for special food to the mothers who followed her request and advice to nurse their babies; she also established means of keeping track of the children after they were weaned. The results of her work were not long in being manifest. In 1901, no more than 50 mothers in this district were nursing their children; in 1918 there were 86 per cent. of the mothers nursing their babies, and the infantile mortality had fallen to 2½ per cent. Naturally, the money expended had steadily increased with progressive usefulness of the work. In 1901 the expenditure totaled 1,000 francs, whereas in 1917 there

was expended 45,740 francs, but the saving of human life to the State was of inestimable value.

A celebrated boxer, now a soldier, has been teaching the doughboys the manly art, and here is what he says about training: The training and condition of the boxer for the square arena is a matter of primary importance. The days have passed in which men were required to go to extremes in training. The era of half-cooked beefsteak is no more. In fact, the boxer in proper training requires no more restrictions, so far as diet is concerned, than any one who desires to be a possessor of good health and a normal body. The boxer rises about seven in the morning and goes through ten minutes' breathing exercises. He stands out in the open air, or at a window, and fills his lungs to their capacity by inhaling through the nose slowly, then opening the mouth and exhaling slowly. This operation should take from five to ten seconds, and will be found greatly to improve the lung power and chest measurement. Breakfast is next on the schedule, and after two hours' rest comes "road work," which should not exceed five miles. It is advisable to cover some hilly course, both to develop your leg muscles and to deepen your chest and wind. The varying nature of the ground covered assists enormously in building up one's physique, and brings into play every individual group of muscles. Following "road work" come the bath and massage. Start your bath with warm water and finish with cold. The muscles should be thoroughly massaged to keep them from becoming tied, so to spak. This completes the morning work-out. An hour's rest, and dinner is ready, which should consist of good, wholesome food. After a rest of three hours comes the gymnasium work, which is the real training of the day. A lively four-round bout with the striking bag is first on the program. This will develop hitting power and speed. Then comes four rounds of shadow boxing. This exercise develops speed, keeps the boxer brisk and "springy" on his toes, and teaches him to maintain a perfect balance as well as the correct way to hit. Rope skipping comes next. It develops the abdominal muscles, endurance, wind, and in fact brings into play all groups of muscles. Boxing practice follows. Six rounds of fast milling is a good day's "work-out" with the gloves. Wind up the day's training by taking exercise to strengthen the stomach muscles, such as lying on the back and raising the legs to a right angle with the body, then sitting up by muscular exertion only. Throwing the medicine ball is also excellent exercise to strengthen the back and arms. Baseball, handball, "soccer" and tennis are dandy sports to help condition the boxer. A shower bath and massage follow the day's training. The muscles should be kneaded carefully to keep them pliable. They should never be allowed to grow hard and knotty, for if they do one will be slow in getting into action.

146 Avenue des Champs Elysées.

Infantile Kala-Azar in France.—Labbé has seen two cases of this exotic disease in French children. The leading symptoms were fever with wide oscillations, hypertrophy of the liver and spleen and marked anemia. The leishmania was found in the blood.—*Le Progrès Médical.*

CANADIAN LETTER.

(From an Occasional Correspondent.)

INFLUENZA IN CANADA—FEDERAL BOARD OF HEALTH FOR CANADA—VENEREAL DISEASE IN CANADA—FOOD CONTROL—ORTHOPEDIC HOSPITAL IN TORONTO—MEMORIAL TO McGILL STUDENTS WHO FELL IN THE WAR—OBITUARY.

Montreal, November 21, 1918.

Influenza has practically burned itself out in Canada. This result, no doubt, to a large extent, has been due to the careful and elaborate precautions taken to curtail its activity. In some of the large cities the disease seems to have wholly departed, while in all the centers of population the number of cases reported have fallen to very small figures. In Montreal, where the epidemic has been especially widespread and virulent, there are now only a few cases. The number of cases reported to the Montreal City Health Department since October 1, totals 18,318 and the deaths 3,124. Now that, to all intents and purposes, influenza in epidemic form has left Canada it may not be out of place to discuss briefly some of its salient features and particularly of those which have been provocative of a good deal of argument. It has been asserted that the pandemic of influenza which has swept the world during the past few months is unlike other pandemics or epidemics, in that certain distinctive characteristics have been present which have been absent in former outbreaks. In the first place its bacteriology has been of a confusing nature. Up to the time of this pandemic, although it was generally allowed that its causation was somewhat obscure, probably most medical men were inclined to attribute it to Pfeiffer's bacillus. However, it must be also borne in mind that during many years, well known bacteriologists have recognized more than one type of influenza, designating a true influenza that in which the Pfeiffer bacillus was isolated. Finkler in "Twentieth Century Practice of Medicine," years ago said that he was of the opinion that there existed a pandemic influenza caused by Pfeiffer's bacillus, and also an epidemic endemic influenza of identical nature which developed after the pandemic infection had run its course, being caused by germs left by the latter. The occurrence of various forms of catarrhal fever, which were often called grippe or influenza by physicians and laymen, was something different. *Inter alia,* it is interesting to note that the first authoritative statement made in America in regard to Pfeiffer's discovery was published in the Medical Record of January 30, 1892. It appears, therefore, so far as the bacteriology of the disease is concerned, at any rate in Eastern Canada, that in the pandemic just dying most of the cases are mixed infections, the pneumococcus, in one strain and another being that recovered, perhaps most frequently. A considerable number of cases have exhibited the influenza bacillus. Also various forms of streptococci have been found. From the clinical, as well as from the bacteriological standpoint, the disease presents many complications, or rather it may be said complexities. According to European re-

ports, on the whole, the 1918 pandemic in its bacteriological and clinical aspects, is similar to that of 1889. In Europe, as on this continent, one great difference has been observed, and that is the age of those affected. In the 1889 outbreak, it is reported that older persons were chiefly attacked, whereas in this present year it was the young who were most prone to infection. Nevertheless, in reading the accounts of pandemics and epidemics of influenza from the year 1510 to this period it would seem that the young have had no immunity or only comparative immunity to infection in days gone by. Indeed, in the Annals of Influenza edited by Theophilus Thomson and published by the Sydenham Society in 1851, Dr. Clendinning writing on the epidemic in England in 1837 commented on the fact that in previous epidemics, it had been the aged who appeared to be comparatively immune. In 1837 he said that the mortality with us in the wards of St. Marylebone Infirmary and elsewhere, amongst populations embracing indifferently individuals of all ages, sound and unsound, was very considerable. He went on to say that few if any cases were lost from influenza unaided by previous disease or subsequent complication. He further specified that pleuropneumonia was excited and proved fatal in a very large proportion of cases. Thomson himself in his concluding remarks stated that the most frequent and important complications were inflammation of the bronchial tubes, lungs, pleura, or of the brain and its membranes; acute articular rheumatism; neuralgia, and cutaneous eruptions; the nature of the complication depending on constitutional peculiarities or on exposure to the exciting causes of the associated disease action about the time of the onset of the attack of influenza. He recorded his opinion that the symptoms have been similar during several centuries, and under very different degrees of civilization.

Another point to which attention has been drawn is the influence a general change of diet may have had on predisposition to infection and on the course of the disease. It has been argued that deranged metabolism due to change of diet, and mainly perhaps to lack of sugar, may have been responsible for the susceptibility exhibited by the young or relatively young at this pandemic. The theory that maladjustment of the diet may be a factor in rendering the individual more susceptible to infection by influenza is ingenious and worthy of consideration. But seeing that the conditions with regard to food and sugar, in particular, have been worse by far in Great Britain than on this side of the Atlantic and that influenza does not seem to have been either so prevalent or virulent in the United Kingdom as in 1889, this argument appears to lose much of its force.

Among other reforms that the war may emphasize the need of and bring about is the establishment of a National Board of Health in Canada. The epidemic of influenza through which Canada has just passed has demonstrated the inability of the machinery now in existence for coping with such a situation and its ineffectiveness for conserving the health and lives of the people. The toll of preventable diseases in Canada is appalling. The war has shown the results that can be obtained from preventive medicine intelligently applied and the medical profession and the public of Canada alike demand that the principles of preventive medicine shall be brought into play throughout the Dominion. The scope of preventive medicine is vast, in fact embraces all projects designed to save human life and improve health generally. The idea appears now to have taken root in the Canadian mind that a Federal Health Department is essential for devising and carrying out schemes calculated to conserve life and to maintain health at a high standard. It appears to be fully recognized by the medical profession here that the existing agencies for saving life and promoting the health of the population are wofully inadequate and it is realized that the problem can be successfully solved only by the creation of a national department of health. At the same time, it is felt that in the preliminaries of this new departure and in the management of the scheme when consummated the doctor must not be left out in the cold. He must be consulted with regard to the drafting of a plan for a board of this kind and must hold a position of authority when the plan has come into being. It is too much the custom here for politicians not only to have a finger in every pie but if possible to allow no one else to get a finger in it. A successful board of health is impossible without the cooperation of the medical profession, but its members must take care that they do not become the puppets of self seeking politicians.

The ravages of venereal disease are arousing apprehension in all parts of the world. In Europe the question of combating its spread is a burning one. No longer is the matter discussed with bated breath and in secret but it is proclaimed from the very house-tops. Some Americans, notably Mr. Bok, have arraigned London as the headquarters of prostitution and have seemed to desire to convey the impression that vice and venereal diseases are in the nature of things more or less restricted to the old world and that on this continent if virtue does not reign supreme, at any rate vicious conditions are more conspicuous by their absence than their presence. This may be so, to some extent, but on the other hand, it would be like the ostrich hiding its head in the sand when pursued by the hunter to aver that venereal disease is not prevalent in Canada and in the United States. If it were not prevalent why should a drastic law be enacted to prevent in some measure the spread of venereal disease in Ontario, and why should a report have been issued recently showing that vice and consequently venereal disease are too frequent in Montreal? The report referred to, according to the Montreal *Star*, November 16, 1918, shows that houses of prostitution are numerous in Montreal and further the charge is flatly made that as the laws now stand and are administered by the courts, there is practically a recognition of such places. The truth then appears to be that prostitution and venereal disease are common in North America and that it is incumbent upon Canada to set its house in order in this respect.

Much dissatisfaction has been expressed from time to time with regard to the manner in which food control is exercised over the restaurants in Canada. The Controllers have ordered that food should be economized, some kinds of food especially, and the general public has willingly and cheerfully acknowledged the necessity for the restrictions and submitted to the curtailment of their food supply. The people have endured the extravagant charges of the retailers but they have entered most emphatic protests against the obviously unjustifiable cost of food in the restaurants. It has been stated on good authority that as much as 500 per cent. profit has been made by the proprietors of these establishments.

It is said that there will be accommodation for more than one thousand soldier patients in the building in Toronto occupied formerly by the National Cash Register Company. It is intended that it should be the central military orthopedic hospital for Canada. McGill University, Montreal, has undertaken to erect on the college campus a convocation hall as a memorial to the large number of McGill students who fell in the war.

Dr. Thomas Cullen who died on September 14, at Baltimore, was a silver medalist of Toronto University in 1890, and from 1892 to 1896 was associate professor of gynecology at Johns Hopkins University.

7. The Ingrown Toenail and the Coup d'Hache.—Douglas H. Stewart suggests a method of dealing with the ingrown toenail which may be regarded as an adaptation of the hatchet technique. Two wooden tongue depressors are fixed firmly with adhesive strips in such a manner that the proximal piece of plaster compresses the blood vessels by surrounding the proximal phalanx of the great toe, thus ensuring a stationary, bloodless operative field that mitigates the dangers of cocaine absorption by furnishing a free exit through the open incision, with a blocked entry through the compression. The distal ends of the two depressors should have their binding plaster strip free of the toe, *i.e.* beyond the outer end. If the wooden depressors are properly placed, a line drawn with a pencil using their edges as a ruler and guide should pass one-eighth of an inch to the mesial side of the hook of the offending nail. Whatever projects beyond that guiding line or protrudes between the guiding edges of the tongue depressors should be sawn off, and this from a point a full quarter of an inch proximal to the lunula to the distal end of the portion to be removed. Thus germ nest, uncus, sound and unsound tissue are removed. Stitching is not necessary, ligation should be avoided if possible, and the scar will not touch the sole of the shoe when walking. Healing is expedited by nonsticking dressings and the absence of tearing off scabs, with employment of a properly cut shoe. The operation is one of extreme simplicity and the patient should walk well in a week; seventy-two hours in bed helps to promote rapid healing.

1. The Rôle of Instinct, Emotion, and Personality in Disorders of the Heart, with Suggestions for a Clinical Record.—C. Macfie Campbell discusses the relation of personality, instinct, and emotion to disease, and especially to disorders of the heart. In disorders which consist of a maladaptation of the patient to his life situation questions arise as to why in one case the symptoms are cardiac, in another respiratory, and in a third gastrointestinal; and whether the patient with cardiac symptoms has a special type of inferiority of the cardiovascular system or the symptoms are dependent on an unsatisfactory instinctive or emotional life, or in most cases are both factors involved. Since, for example, the effect of a terrifying experience varies in different types, the result cannot be explained by a mere reference to the situation but must be considered in relation to the individual. It may well be that the persistence of cardiac symptoms in such cases may be due to a constitutional idiosyncrasy or acquired inferiority. It is important to recognize, moreover, that every experience tends to modify the later reaction of the organism; the patient may be left with an increased immunity or an acquired sensitiveness. (The soldier, unnerved by his experiences with high explosives, may react with extreme sensitiveness to abrupt noises, and in this reaction cardiac symptoms may predominate.) In considering the relation of heart cases to cases of war neuroses, two factors must be studied: (1) The intimate mechanism of the cardiac inferiority; (2) the emotional and situational factors that precipitate and foster the symptoms. The relationship of the cardiac symptoms to other manifestations of inferiority must also be considered; thus a lack of virility and efficiency may be secondary to an inferior cardiovascular apparatus, or, cardiac discomfort and irregularity may be explained by the undue demands made on the heart by an unstable or oversensitive emotional life or by a sexual life which, owing to the constitutional inferiority of the patient, is not subjected to control. This author has examined thirty-three patients and found that their constitutional inferiority could be referred to three types: (a) An inferiority manifested in prolonged physical invalidism, with little or no definite intelligence defect; (b) an inferiority in which defective intelligence is a prominent factor; (c) an inferiority in which the instinctive and emotional life is of poor quality, while the intelligence is fair. In addition to the clinical aspect of these cases, the military and reconstructive aspect must be considered, and it is advisable, therefore, to include in the clinical record a summary statement as to the personality of the patient, and as to any experiences and situations that seem to have a direct bearing on his disorder. The constitution, or innate equipment of the individual, can be estimated by a study of the stock from which he has sprung, with special attention to the presence of epilepsy, insanity, alcoholism, etc., and his early reactions to the test of

life before training and experience commenced to play a predominant rôle. In addition to the nervous efficiency of the patient, his general efficiency as evidenced by his school record and wage-earning capacity should be taken into account; also his behavior to his comrades, his steadiness at work, and responsiveness to standards of honesty, truth, and decency. In estimating the degree of disability caused by cardiovascular symptoms the whole situation must be considered. Obviously, the military situation is an important factor, for restoration to health leads to the trenches and the toil of war, for which the patient has a deep-seated repugnance, however loyal to duty his conscious, official self may be. In civilian life this applies with equal force where the various causes of nervous invalidism are covered up by the conventional explanation of overwork.

3. A New Technique of Heart Massage, With a Case of Resuscitation.—Captain T. C. Bost describes a new technique of heart massage which was carried out in a case of suspended heart action following an anesthetic. Patient, a soldier, had been severely wounded in October, 1917, both knee joints being involved. There was prolonged treatment and several operations and, in March, 1917, as the patient was losing ground, laparotomy was decided upon to determine the presence of any abdominal abscess and the condition of the kidneys. After a preliminary hypodermic of atropine and morphia, chloroform was carefully administered by the open method. Within a few minutes respiration ceased and patient became pulseless. Artificial respiration was commenced immediately but without effect. As the case appeared hopeless, Captain Bost inserted his hand into the thorax, passed it up under the sternum to the base of the heart and began slow pressure. At first the organ was completely flaccid; in about 12 seconds a muscular twitch was felt, and was followed by a feeble contraction, which became strong and regular. Pulse was felt, color returned; massage was stopped, pituitrin injected, and artificial respiration continued. A rapid exploration of the abdomen was made. Patient lay comatose and death occurred 77 hours later. The technique of procedure followed was: An abdominal incision was made four inches long in the median line, extending from above the umbilicus well up into the xipho-sternal notch. The left costal cartilages were well retracted, bringing the anterior diaphragmatic insertion well into view. (There should be a pillow under the waist.) By a two-inch incision beginning one inch to the left of the median line, carried outwards behind the costal margin, the fibers of the diaphragm were cut near their insertion. A blunt instrument was pushed in to open the pleural cavity, and the opening rapidly dilated with two or three fingers of the right hand. The hand was then passed into the thoracic cavity anterior to the pericardium, and upward, the thumb behind the sternum and the fingers embracing the entire organ in the pericardium. The right auricle and ventricle were compressed by the thumb and the heart effectively massaged. In this incision no vessels are injured, the liver and stomach offer no obstruction and the pericardium is in no risk of being opened. During the massage the parts can be pressed round the wrist of the operator so that air is not sucked in, and there is no tendency to collapse of the lung. The incision is easily closed and made air-tight. In the case in question, it is pointed out by Major Neve that had the method been adopted a few minutes earlier, or if the kidneys and lungs had been healthy, the patient might well have recovered. The author concludes: (1) That this case illustrates the unique value of heart massage, and that the human heart can be resuscitated after a variable length of time—in this instance after 25 minutes. Nothing else could have restarted the cardiac action. (2) That all cases of suspended heart action following an anesthetic, regardless of theoretical etiological factors, after a certain interval, should be given heart massage, and that cases of asphyxia should also fall within this group. (3) The length of interval should probably vary with individual cases, but direct massage should rarely be done under five minutes (unless the abdomen be already open); it should certainly be done after eight minutes though a longer interval need not bar the operation. Simpler methods of resuscitation should begin in the first minute, but should not be uselessly persevered in to the neglect of more efficient measures. (4) Subdiaphragmatic massage may suffice, especially in children, if promptly undertaken. But if only the apex is reached and the heart remains unresponsive the diaphragm should be incised and the base of the heart be massaged without further delay. (5) That no surgeon, even if relatively unskilled, should be content to abandon a case without giving his patient the benefit of direct cardiac massage. (6) The author claims that this new technique offers a simpler method of approach and is a decided improvement upon all other ways of doing direct heart massage, as it involves less risk of hemorrhage, trauma, and shock, and can subsequently be more quickly and satisfactorily closed.

3. Epidemic Encephalitis.—Arthur J. Sall discusses the epidemic of encephalitis which appeared in England in March of the present year. He asks is this or is it not an epidemic of poliomyelitis? If it is not, it may be either an entirely new disease, or one that until recent times has not been observed in epidemic form. Clinical resemblances between these cases and poliomyelitis were recognized from the first, but there was absence of localized limb paralysis commonly seen in acute poliomyelitis. The clinical differences have been clearly stated by Kinnear Wilson; severe and prolonged lethargy and asthenia which occurred in most of the cases of encephalitis are not recorded as occurring in typical cases of poliomyelitis, sporadic or epidemic. "Sleeping Sickness" would not be an inappropriate name for the epidemic, but this could hardly be said of poliomyelitis; in fact, if the palsies were taken away from these cases of encephalitis, little would remain that was common to the two conditions. Even the palsies presented striking differences in these two diseases in their mode of onset, situation, and results. In poliomyelitis the onset is rapid and maximal, the regions affected being those innervated from the spinal cord, and the distribution is often unilateral; moreover, permanent residual effects are often left in the area first attached. In the epidemic under consideration, the paralyses were typically of gradual ingravescent onset and the regions affected were those innervated by cranial nerves; moreover, distribution was bilateral, and as far as is known no permanent residual effects were left. A selective action appeared to be at work, as is seen in many nerve poisons. The argument that poliomyelitis in its epidemic form is characterized by the multiplicity of the sites affected rather accentuates the clinical difference between the two diseases, as the cases during the March epidemic were notable for the uniformity of the sites

affected. The author states that he has no proofs to bring forward as regards the possibility of this being an old disease only recently recorded in epidemic form, but that such a line of inquiry seems worth consideration. In any case the disease cannot be spoken of as a new disease until these alternatives have been set aside, and the final decision must rest with the pathologist.

Observation of a Serious Case of Colospasm and Its Premonitory Stage on a Radioscopic Screen During an Enteric Ataxic Paroxysm.—E. Schlesinger refers to radioscopic observations recorded by other writers during the gastric crises of locomotor ataxia, in which spasmodic contraction of the middle portion of the stomach, with pushing of its contents toward the cardia, was seen. The writer describes an absolutely similar spasmodic paroxysm occurring in the descending colon. The article is illustrated by three radiographs taken before, during, and after the paroxysm. This was characterized by the formation of an intense contracture along the entire extent of the descending colon. The opaque mass was reduced to an extremely narrow shadow, from which numerous lateral diverticuli, likewise very narrow, shot off and overlapped each other. Schlesinger interprets this picture as a spasmodic contraction of the colon, involving both the circular and longitudinal fibers. The image also shows that the opaque mass ebbing back from the descending colon becomes lodged in the transverse colon and not in the sigmoid flexure. There is, consequently, a sort of antiperistaltic movement at the commencement of the paroxysm. Besides this, the colon and sigmoid flexure become straightened out. The writer recalls, from this point of view, that electrization of the vagus nerve in cats from whom the brain has been removed produces the same picture as that of a gastric crisis of tabes dorsalis, such as has been observed by Lüdin in subjects afflicted with tabetic crises of this organ.

Treatment of Cutaneous Affections by Injections of Oil of Turpentine.—F. M. Meyer has tested Klingmüller's procedure, which consists of a 20 per cent. solution of turpentine injected in the gluteal region every third or fourth day at the dose of from one-half to two cubic centimeters. The effect of this treatment appears to be very favorable in the dermatoses in which suppuration plays an important part, viz., furunculoses, trichophytides, etc. This treatment should be combined with the usual therapeutic measures employed in these cases, especially radiotherapy.

September 10, 1918.

The Necessity of Albumin in Metabolism.—C. Röse and R. Berg start from the following fundamental datum, namely, when food offers an excess of acids, a decomposition of the somatic albumins into varied nitrogenous molecules takes place, among which ammonia serves for saturing the acid in excess. The other nitrogenous substances are in the greater part eliminated by the urine. Food rich in acids, therefore, appears more wasteful as far as albumin is concerned than a diet more largely composed of basic matter. The researches of the writers carried out on the ingesta and excreta of two subjects placed in very strict conditions of observation entirely support these conceptions. After promising to treat of the subject more at length in a future publication, they offer conclusions relating more especially to the diet of the population during penury of food. The need of albumin attains its minimum when the diet offers a basic surplus; this surplus should be calculated for a man of 70 kilograms, working moderately, at 25 milligrams in equivalents. The ignorance of this fact has been the means of overestimating up to the present time the number of calories absolutely necessary. It is for this reason that the war diet of the year 1916-17, with 1421.7 daily calories, did not result in those disastrous results which might have been anticipated. On the other hand, certain periods, such as April to July, 1917, were characterized by a very serious aggravation in the state of nutrition of the people. These periods coincided precisely with a relative acidification of the diet from a lack of potatoes. When this tuber reappeared in the markets the general health of the population improved at once, although the daily amount of albuminoids or the total number of calories was not increased.

A New Method of Forming a Cutaneous Sulcus in the Preparation of Stumps in Sauerbruch's Method.—P. Erlacher describes an operative procedure which gives a sulcus entirely covered by skin and is submitted to muscular action. The muscle is raised out of its bed and laid in the cutaneous sulcus and then is fixed in place and covered by the latter.

The Hemorrhagic Diatheses.—W. Stepp gives a summary of present-day views on these diatheses, among which he also includes certain affections which have nothing diathetic about them, such as scurvy and the infectious purpuras. As far as hemophilia is concerned, Stepp recalls the curious hereditary transmission of the process (he might have taken some of the ruling Hun families as typical examples) and points out that hemeralopia and Daltonism offer a similar hereditary transmission. Scurvy should be included among diseases of the nutrition according to the writer, who excludes an infectious origin from this process. This fact has been proven, on the one band, by the experiments of Holst and Fröhlich (of Norway) on guineapigs fed upon a single kind of cereal and, on the other hand, from the data derived from the present war, during which scurvy has developed among the crews of ships making long cruises, as well as among Austrian troops fed upon bread and canned goods. Stepp attributes an undoubted infectious etiology to rheumatoid purpura without offering any reason for this opinion. He merely insists upon the frequent coexistence of purpuric states and lesions of pulmonary tuberculosis. However, tuberculosis only favors the production of purpura which would not otherwise develop than from the effect of food factors similar to those which enter into the etiology of scurvy. Certain physiological considerations on blood coagulation bring the writer to the question of some modern medications: coagulene of Kocher and Fonio, a tissue juice containing a large amount of thrombokinase; claudene, an extract of pulmonary tissue, possessing a marked power of coagulation. The lipoids play a preponderant part in the action of both these products.

Injections of Turpentine in Some Cutaneous Affections.—I. Sellei has obtained tangible results in impetiginous eruptions with turpentine injections. In the pyodermatitides and furunculoses the effect of the injections is less certain and does not compensate for the fever and pain resulting from their use. In chronic prurigo and simple pruritus this treatment seems to have given splendid results. The writer, who has also experimented with injections of sterile milk in cutaneous affections, believes that the latter treatment has given better results than injections of oil of turpentine.

Scarlatinous Endocarditis.—Nobécourt considers this affection in its double incidence in civilian children and soldier adults. The percentage in the former was computed by Broadbent to be about one-half of 1 per cent. —of more than 22,000 cases of the infection that was the percentage of endocarditis encountered. No such material is available for troops, but the same percentage for these subjects appears to average around 2.5, the limits in individual epidemics ranging from very high to zero. These figures could doubtless be much increased if murmurs of all kinds were included, but extracardiac murmurs occur in all high fevers and possess no special significance for scarlatina. Two well marked types of this lesion occur in scarlet fever, one simple and of early appearance and the other infectious, ulcerating, and vegetating, of relatively late supervention. The author regards them as both strepto-

coccic complications, in the great majority of cases. When endocarditis develops there is usually a general rheumatic syndrome of angina or other local manifestation and joint lesions. An entire syndrome may therefore be superadded to the original infection. In some cases the arthropathies may be minimal. The rheumatic character is well shown by the prompt response to aspirin, although it must be borne in mind that spontaneous disappearance also occurs. In the soldier scarlatinous endocarditis supervenes late rather than early. In a small number of cases studied for the purpose permanent damage to the heart resulted in 28.5 per cent, the victims presenting mitral lesions. This percentage is lower than that of children, in whom more contract permanent damage than escape scot free. In a minority of cases pericarditis or myocarditis is present as a complication.

Malarial Mastitis.—De Brunn reports a number of cases seen in a military hospital and believes that this lesion is by no means rare. The cases quoted, personal and other, appear to have been all in males, although one of the reporters is a woman physician. This mastitis is a complication of secondary malaria, no primary or tertiary cases being on record. The affection is unilateral or bilateral. The chief symptoms mentioned are pain and extreme tenderness, which are resistant to treatment. Pain may be radiated over a wide extent. In some cases it is difficult to support the weight of the bed clothes. If the patient stand up, he experiences relief. The degree of tumefaction may be very slight, or it may be considerable, and the gland proper is apparently much less involved than the cellular tissue. In some subjects a little colostrum may be squeezed out.

Finska Läkaresällskapets Handlingar.

March, 1918.

Case of Pylorospasm.—Mellin describes a case of pylorospasm due apparently to a powerful external shock. The patient was a female infant four weeks of age. At birth she had weighed 3650 gms. The father was healthy, mother nervous. The infant had had both the breast and cow's milk from the start, had thrived well and had gained 545 gms. The stools were normal and there was seldom vomiting. Restlessness was but little in evidence. In the fourth week the patient was exposed to a shock, the dwelling having been struck by a shell from a war vessel which tore loose a portion of the granite wall and shattered all the windows. From this moment the pyloric disturbance began. The child became very sensitive to external irritation, and the slightest noise caused it to wince violently. When for the first time after the event it was offered nourishment it drank greedily for a few seconds, but then suddenly expelled the nourishment in violent efforts at vomiting. This sequence occurred at every subsequent attempt to feed the patient. At first vomiting occurred as soon as 20 or 30 gm. had been swallowed, but later—after a few weeks—the patient could ingest 40 or 50 gm. before rejection. It was noted eventually that if the child at once was offered the same quantity of food that it had just rejected, it could retain it. Further it became evident that at night, when the room was perfectly quiet, the child could retain the original portion. As soon as daybreak, however, even the least noise was enough to provoke vomiting of the first dose of nutriment. By the third week the child could retain from 60 to 70 gms., in the fourth week 70 to 80 gms. and in the fifth week 100 gms. of food, and began to thrive. It became so tranquil that even the loudest noises did not bother it. Vomiting decreased in frequency until in the fifth week it occurred but once or twice in twenty-four hours. In the sixth week nearly all symptoms had disappeared. Treatment with valerian, bromides, and chloral had not exerted any noticeable influence upon the disease. The case was, in brief, a traumatic neurosis.

Correspondenz-Blatt für Schweizer Aerzte.

July 27, 1918.

Diagnostic Significance of the Leucocyte Blood Count in Infectious Diseases.—Stäubli mentions three phases of this problem which require sharp differentiation. First comes the purely local infection. Second, either the microorganism or toxin enters the blood stream. Third, the infectious principle penetrates into some locality in which white corpuscles are generated and stimulates their production. Whenever a chemotrope substance reaches a given tissue—or is formed therein—the leucocytes leave the capillaries and collect in a local accumulation. The resulting shortage in the blood is at once made good from the bone marrow. At first there may be a distinct leucopenia with especial reference to eosinophiles. The chemotrope substance eventually reaches the marrow and other tissues which produce leucocytes and stimulates production in excess. The katabolic products of the leucocytes, however, can exert a paralyzing action on the genesis of new cells, which keeps production down. If we plot curves side by side of the total leucocyte and eosinophile counts we may distinguish between various infectious diseases. Thus in measles we see a general leucopenia plus diminution or absence of eosinophiles. In scarlatina the conditions are reversed—there is hyperleucocytosis with increased eosinophiles. Scarlatina is the only bacterial disease to show this behavior, and this fact lends weight to the belief that this disease is not of bacterial origin. The same blood count is found in trichinosis, a non-bacterial affection. Interesting is the fact that every known streptococcus infection exhibits lowered eosinophile count, so that scarlatina should not be in any sense a streptococcus disease. The blood count easily excludes streptococcus angina and the septic sore throat of streptococcus origin. In variola we see hyperleucocytosis with eosinophiles normal or but slightly varied. The leucocytosis consists very largely of mononuclears, large and small. This count will promptly exclude varicella, for in the latter the leucocytosis may be slight or even absent. Care must be used in differentiation, but it is safe to depend on these axioms: leucopenia at once excludes variola; strong leucocytosis makes variola very probable.

Hygeia.

June 30, 1918.

Case of Error of Sex.—Lundén reports a case of pseudohermaphroditismus masculinus externus in which the general appearance was exquisitely feminine, resulting in error of sex. Three days before consultation the patient had complained of a tender swelling in the left groin, which caused a visit to the author. Examination showed the existence of bilateral inguinal hernia. Bimanual exploration showed absence of uterus and ovaries, while the vagina was represented by a short cul-de-sac. Operation was performed for incarcerated inguinal hernia of the left side. The sac contained what was apparently an ovary. The right side was operated upon with the same find, and the organ was replaced in the abdominal cavity. These bodies, however, were recognized as testicles; and on the left side there was purulent epididymitis, as a result of which orchidectomy was performed. Should the testis of the right side have been extirpated because of possible malignant degeneration? It might better perhaps have been allowed to remain in the groin, where it would have been readily accessible. By leaving the organ behind, the patient had legal evidence of the sex, in so far as it showed that this was not feminine. Marriage as a woman was, of course, out of the question in any case, as vagina and uterus were nonexistent. It is worthy of mention that a "sister" of the patient was evidently an hermaphrodite of the same type, while an "aunt" probably showed the same malformation. Examination was refused by the two individuals, so that the cases cannot be placed on record.

Typhus in Paris Ragpickers.—Netter and Blaizot have recently seen a small number of cases of typhus in subjects living under wretched hygienic conditions, notably ragpickers infested with lice. Diagnosis was very difficult save for the expert and the cases would have passed for typhoid or paratyphoid. We know now that the spread of typhus may be easily checked. The authors compare conditions with those in New York, where Brill's disease is not subjected to quarantine.—*Bulletin de l'Académie de Médicine.*

Book Reviews.

THE PROTEOMORPHIC THEORY AND THE NEW MEDICINE. An Introduction to Proteal Therapy. By HENRY SMITH WILLIAMS, B.Sc., M.D., LL.D., Member of the National Committee for Mental Hygiene and of the Hygiene Reference Board of the Life Extension Institute; successively Pathologist to the Iowa State Hospital at Independence; Assistant Physician to the Blackwell's Island and Bloomingdale Asylums, and Medical Superintendent of the New York Infant Asylum and the Randall's Island Hospitals, New York City. New York: The Goodhue Company, 1918.

THE modern employment of vaccines and sera in the prophylaxis and treatment of various diseases has revealed the fact that, in addition to their specific action, they often exert also a non-specific effect in stimulating the production of antibodies which have a curative action in the case of many and diverse affections. The antityphoid vaccine, for example, seems to have a therapeutic action which, if not actually curative, is at least ameliorative in the case of various skin diseases, "rheumatic" affections, malignant growths, etc. In explanation of this the theory has been evoked that the parenteral absorption of any foreign protein excites the defensive mechanism to the formation of antibodies capable of hydrolyzing not only that special protein but other foreign proteins as well. The amplification of this theory and its application in therapeutics form the subject matter of this very interesting book. Connected with this theory is also that of the mechanism of the hydrolysis so initiated, viz., that "the mononuclear leucocytes are the agents vitally concerned in beginning hydrolysis, and the red corpuscles the agents concerned with the completion of decompounding of foreign proteins in the parenteral system." This is what the author calls the proteomorphic theory.

In the therapeutic application of the theory of antibody formation under the stimulus of a foreign protein, Dr. Williams uses, not specific vaccines or serums, but nonbacterial vegetable proteins, which he calls proteals; the method of treatment therefore is known as proteal therapy.

Space forbids more than this very incomplete statement of the theories and the practical applications of the same, recounted at length and most interestingly in Dr. Williams' book. Whether one accepts the theories or not, he will enjoy the author's clear presentation of them; he is also at liberty to doubt the results obtained from "proteal therapy," but his scepticism will be ingrained if it refuses to give any credence whatever to the facts presented in this book and in the periodical literature of the past few years.

THE INTERNATIONAL MEDICAL ANNUAL. A year book of Treatment and Practitioners' Index. 1918. Thirty-sixth year. Price, $4. New York: William Wood and Company.

A WORK of this kind is a necessity to the library of every physician and every student. Some prefer to take their "new material" in monthly doses, some quarterly, and some once a year. For the last, the present volume will prove particularly attractive. The reader will find within the pages of this work an account of the relation of the great war to medicine and surgery; also a description of the newest methods in the treatment of wounds, shell shock, trench throat, gas gangrene, etc. In addition to this, there will be found a résumé of the latest work in Tropical diseases, Respiratory diseases, Diseases of the digestive system, Gynecology, Syphilis and gonorrhea, Fevers, Skin diseases, Constitutional diseases, Radiotherapy and electrotherapeutics, and Mental diseases. The material contained within the volume has been well selected and judiciously condensed and prepared for the busy searcher after knowledge. The arrangement is alphabetical, and the volume closes with a good index.

PRÉCIS DE DERMATOLOGIE. Par J. DARIER. Médecin de l'Hôpital Saint-Louis. 2me édition revue et augmentée. Prix 18 francs. Paris: Masson et Cie., 1918.

THE first edition of this work appeared 9 years ago and inevitably the supervention of the great war has delayed the publication of the second edition. Hence the disparity is more marked than usual between a first and second edition. The number of pages of text have increased nearly 25 per cent. and the number of illustrations over 50 per cent. The number of chapters is increased by one only, devoted to the dermatoses of leukemia. Among the subjects requiring complete revision are anaphylaxis, phagedenism, sarcoids, gangrene, dermatomycoses, xanthoma, dyskeratoses, diphtheritis cutis, leishmanioses, cutaneous leucemia, tophi, heredo-syphilis and tuberculosis. We are informed that the volume is being translated into English. The first edition was translated into German. These statements need no comment.

NURSING ETHICS. A Lecture by T. PERCY C. KIRKPATRICK, M.D. Fellow and Registrar of the Royal College of Physicians of Ireland. Price 35 cents. Dublin: University Press, 1917.

THIS booklet was first published in 1915 and is decidedly novel in scope, although there seems no good reason why this should be so. The nurses have more obligations than the physicians, for in addition to their duties to patients and to one another they have additional ethical obligations to the medical profession. The author's conception of the nurse, however, is based largely on the idea of one who nurses the poor and humble rather than the well to do and who is sent out by the hospitals, to which she is therefore responsible. However, he gives space to the private nurse, whose ethical obligations are, he states, of quite another order. This effort might form a nucleus for a much more pretentious one, with a suggestion of a codification of nursing ethics.

THE EVOLUTION OF NATIONAL SYSTEMS OF VOCATIONAL RE-EDUCATION FOR DISABLED SOLDIERS AND SAILORS. By DOUGLAS C. MCMURTRIE. Prepared at the Red Cross Institute for Crippled and Disabled Men Issued by the Federal Board for Vocational Education, May, 1918. Washington: Government Printing Office.

THE Federal Board was organized in the summer of 1917 so that the present volume is the outcome of less than one year's activities. The latter include a Research Division which has investigated all of the movements and institutions of kindred scope throughout the world. The countries thus covered are France, Belgium, Great Britain, Italy, Germany, Austria-Hungary, Canada, Australia, New Zealand, India and South Africa. Nearly all of the national movements for the rehabilitation of cripples had their inception in the present war, but after the Boer and Russo-Japanese wars limited movements of the same sort were begun in Petrograd and South Africa. The present Bulletin is only one of three which deal with this subject and deals only with the evolution of the movement. The others will cover respectively the subjects of vocational rehabilitation and training of the teaching body.

ESSENTIALS OF DIETETICS. A Textbook for Nurses. By MAUDE A. PERRY, B.S. Formerly Dietitician and Instructor in Dietetics at Michael Reese Hospital, Chicago, etc.; Red Cross Dietetician for Base Hospital Unit No. 14. St. Louis: C. V. Mosby Company, 1918.

THIS little volume of 150 pages is divided into two parts, devoted respectively to essentials of dietetics and diet in disease. By omitting the usual pages on pages of recipes and menus the author conveys as much information as some far more bulky volumes. The work is well adapted for both teaching and self instruction, the essentials being summed up in the form of questions at the end of each of the twenty chapters.

PRINCIPLES AND PRACTICE OF FILLING TEETH. By C. N. JOHNSON, M.A., L.D.S., D.D.S., Professor of Operative Dentistry in the Chicago College of Dental Surgery. Editor of the *Dental Review*. Fourth edition. Revised and enlarged. Price, $3.00. Philadelphia: P. Blakiston's Son & Co., 1918.

THIS volume, according to the preface, has undergone a thorough revision. In comparison with the edition which appeared in 1902 it has shrunk slightly in actual bulk but the amount of text appears to be larger, as is the number of illustrations. The twenty chapters of the older edition have been increased by two, one of which is devoted to the uses of the *x*-ray and the other to silicate cements.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Thirty-First Annual Meeting, Held at Detroit, September 16, 17, and 18, 1918.

THE PRESIDENT, DR. ALBERT GOLDSPOHN OF CHICAGO, IN THE CHAIR.

The Benefits of Stab-Wound Drainage in Pelvic Infections.—Dr. H. WELLINGTON YATES of Detroit drew the following conclusions: "(1) It should be our constant endeavor to close without drainage in so far as safety will permit. (2) Drainage materials should be removed earlier than the general practice now obtaining. (3) The great majority of all infected areas in the pelvis are suitable for cul-de-sac or stab-wound drainage. (4) The abdominal incision should be left free to close by primary union. (5) Stab-wounds are securely and quickly united after the drainage is withdrawn, with no fear of subsequent hernia. (6) The musculature of the areas usually chosen for stab-wound drainage is our greatest asset to a speedy closure of the drainage opening."

Dr. GORDON K. DICKINSON of Jersey City, N. J., stated that drainage was a misnomer. We did not talk accurately. He did not think that gauze drained when it was stuck in a wound. It was a local irritant and because of that property it walled off to a certain extent the local processes and made things fairly safe. But we did have wonderful drainage in the abdomen. Some ten years ago he made what he thought was the first research study of the literature and of his own work regarding the value of the omentum in abdominal drainage, and he came to the conclusion then that the omentum, properly applied, would drain more in ten minutes than any gauze would take out in a day.

Dr. J. HENRY CARSTENS of Detroit said that the late Dr. Joseph Price was a firm advocate of drainage. Some fifteen years ago the association held a meeting at Pittsburgh, and he and a number of others performed operations at the hospitals there. He had the worst kind of a case to deal with, with extensive adhesions and pus. Dr. Price was there and talked about drainage, and the speaker said we could get along without drainage in many instances. He operated on this pus case, cleaned out the abdomen thoroughly without washing it, and closed the incision without drainage. Other men who operated on patients at that time and drained lost their patients, but luckily for the speaker his patient recovered. Since then he had resorted to drainage very little.

Dr. JOHN W. KEEFE of Providence, R. I., said that drainage was a subject that we all had to contend with from time to time. Hard rubber drainage tubes in the abdomen were largely discarded to-day, so much so that when a report from a certain cantonment came to Washington of a case of appendicitis with a fecal fistula the officer to whom this report was sent wrote to know why that patient had a fecal fistula, and it was found that a drainage tube had been used. Word was sent back that that officer would be court martialed for placing a rubber drainage tube in the belly following an operation for appendicitis. Most surgeons felt that a hard rubber drainage tube should not be put next to the intestine. There was no question but that an incision into Douglas' pouch for drainage was a desirable thing in a few cases. In looking back over the literature of gynecology one could see how many patients died from placing drainage tubes in the pelvis and nurses withdrawing the serum that formed every half hour, or sometimes every three hours. As soon as surgeons began to close the belly and not interfere with nature these patients recovered.

Dr. CHARLES L. BONIFIELD of Cincinnati stated that just as soon as surgeons began to keep drainage tubes out of the abdomen, abdominal surgery progressed and better results were obtained. While this was partly true, it was not the whole truth. One of the reasons why surgeons secured better results now than formerly was because they were improving in their technique and drainage became less necessary.

Dr. HUGO O. PANTZER of Indianapolis concurred heartily in what Dr. Bonifield had said. However, there were cases in which we could not get along without some form of drainage. There were cases in which there was an accumulation of pus indicating that the peritoneum was unable to cope with it at that time, and hence some form of drainage was necessary.

Dr. YATES, in closing, stated that drainage had been made use of altogether too often in the past, and drainage tubes should be used in the future much less frequently than they had been heretofore. However, there were certain instances in which it was essential to drain, and in still others it seemed best to drain from above. His paper was written largely for the purpose of establishing when and where not to drain. He suggested that the primary incision should be left to itself and to heal without discomfort.

Pathological Conditions of the Pelvic Viscera, the Result of Induced Abortions Causing Sterilization.—Dr. FRANCIS REDER of St. Louis stated that this paper was prompted by eight cases of sterilization, the result of induced abortions. All the women were married, in good health, and none over 35 years of age. In each instance the abortion was induced soon after the first period had been missed, usually the second or third week. It was of interest to note the number of abortions induced in these women. Three women were relieved 5 times in 2 years; 2, 6 times in 2½ years; 1, 9 times in 3 years; 1 11 times in 3 years, and 1, 14 times in 5 years. As years passed and the thoughts of these women by some noble principle were being directed into channels which led to the lofty ideals of life, they became obsessed with the wish to have a child. The recall of former experiences, when it seemed so easy to become pregnant, only made darker the pages of remorse in their lives, and now, when willingness and eagerness were uppermost in their hearts, they found themselves sterile. The chapter of their lives that followed teemed with consultations in the office of the gynecologist. They cheerfully submitted to treatments which buoyed them with hopes from month to month, only to find that at the end of their course of treatment they were just as sterile as they were before they consulted the gynecologist. The treatment was generally of a routine nature and consisted in dilatations, curettements, the introduction of intrauterine wire pessaries, tampons, and the so-called uterine tonics. Most of these cases were under treatment for many months. The physical examination in cases of this character revealed nothing definite relative to an intrapelvic condition which might be present. During the last six years he had operated on eight women in the hope of relieving their sterility. The operation, an exploratory abdominal section, was in each case performed after these women had been subjected to therapeutic and minor gynecological measures for a time which seemed sufficiently long to give convincing evidence that without any further intervention the sterile state bade fair to remain permanent. Summing up the operative findings in these cases, in all except one the ostium abdominale of both tubes was closed. This was the positive factor in rendering the women sterile. In five of the cases there was a bilateral hydrosalpinx. In two there was a unilateral hydrosalpinx. The opposite tube in those cases was collapsed and presented a sacculated appearance, the lumen giving evidence of a number of strictures. In one case no hydrops of the oviducts was present; they, however, were sacculated and the uterine ends were stenosed. In each case the tubes were dislocated into Douglas' pouch and usually bound down with firm bands of adhesions and false membranes. On the left side the tube was buried under the sigmoid, while the tube on the right side was attached by side adhesions to the cecum and appendix. Examination of the ovaries revealed that pathological processes had invaded these organs. No ovary was found in its normal position, all were more or less prolapsed and adherent to the tubes. In several instances there was a matting together of ovary, tube, uterus, and rectum. Some of the ovaries were twice their normal size and all gave evidence of cystic disease, *i.e.* a cystic degenerative process. As a result of these operative measures, two of the women conceived and went to full term within 20 months after the operation. They were the youngest

of the series and were respectively 26 and 30 years of age. The remaining six women, operated on within the last four years, were still in a state of sterilization.

Cesarean Section Under Local Anesthesia.—Dr. William Mortimer Brown of Rochester, N. Y., said that in doing this operation under a local anesthetic there were two important elements that were necessary for success. The first was to get the confidence and cooperation of the patient and the other was a thorough infiltration of the operative area and an exquisite delicacy of manipulation. No matter how careful one might be in the preparation one could not hope to block all of the underlying nerves and it was very easy to pass from easily borne discomfort to unbearable pain. It was not difficult to anesthetize the abdominal wall so completely that the peritoneum might be opened without appreciable pain. The fundus was without sensation and was readily incised without the knowledge of the patient. The pain was attendant on the dragging or manipulation of the organs, either uterus or intestines. The ideal operation must be done without soiling the peritoneum, without lifting and pulling on the uterus. With these requisites in mind, he had found a method which he had employed for several years, of peculiar advantage. It was his custom, after the abdomen was opened and the uterine incision partly made, to fasten the uterine out to the abdominal incision with four or five ordinary towel clamps. These clamps held the uterus to the abdominal wall and prevented the blood or amniotic fluid from getting into the peritoneal cavity. They were left in place until the uterine wound was largely closed and did away with most of the traction on the uterus, and made it unnecessary to pack gauze into the abdomen.

Gall-Bladder Disease and Its Differential Diagnosis.—Dr. John F. Erdmann of New York City said that the sex preponderance was in the female and, as Deaver aptly put it, beware of the female, fair, fat, and forty or past, who belched wind. Nevertheless, in the great proportion of his case records, the year of onset or early visitation of symptoms was between 25 and 27, a few as early as 18, and one, a common-duct case in which he had operated, gave a history of jaundice (following colic) at 14, the operation being done by him when the patient was seventeen. The colic or cramp was described as being in the upper right quadrant, either without extension or with extension into the back, lumbar zone; up the back, under the shoulder blade—in the space between the shoulder blades; in the left shoulder and occasionally in the left and right neck. Frequently and usually when the stone was in the cystic duct, the colic was said to travel across the midline upwards—under the left nipple and breast (pseudoangina). The attacks were very prone to occur between 7 P.M. and 1 A.M.—thusly markedly differing from the pain in ulcer of the duodenum. Jaundice was a sign made much of years ago but now accepted only as a confirmatory evidence of some obstruction to the outflow of bile, or some destructive blood condition, as in hemolytic jaundice, etc. Frequently a greater loss of weight was seen in a given short period of time in gall-bladder involvement than in many cases of malignancy. This loss was to be assigned to several sources—the limiting of diet; improper metabolism due to impaired bile, and also to pancreatic associations. Pruritus, this disagreeable sleep and peace destroyer, was in early evidence in all patients with jaundice and frequently with those in whom the pancreas was involved. In examining these patients evidences of pruritus presented themselves as long scratches or small petechial spots all due to both conscious and unconscious scratching.

On straining stools stones might be found, but the infrequency of finding stones and the definiteness of symptomatology led the practitioner of the present day to forego the procedure. The preponderance of ulcer of the duodenum was in the male. The physical make-up, as far as his cases presented themselves, was in those of slender wiry variety and frequently classed as neurasthenics, usually between 25 and 35 years of age, and non-alcoholics in habit. When obstruction was well advanced, the patient lost weight and was very prone to have a chain of mental symptoms, equal to those of starvation. In addition to these subjective symptoms the analyses of stomach contents might show blood and usually did show hyperacidity both in combined and free HCl, with the other undigested contents, etc. Acute perforation of the ulcer might take place without any preceding symptoms of moment. The onset was a pain of intense character, requiring morphine in liberal quantity; shock, board-like rigidity in the upper right quadrant; thoracic breathing and later pain in the right lower quadrant simulating appendicitis. This pain was due to irritation of the peritoneum by escaping contents of the stomach and duodenum. Operative interference in the early stages might be followed by overlooking the ulcer because of its not being calloused or indurated. Lues, with its abdominal crises, must always be considered as a confusional factor of great weight in upper abdominal disease. Recently in a definite ulcer history and so diagnosticated a very markedly chronic appendix was removed from under the gall-bladder and directly over a duodenal ulcer the size of a 25 cent piece. In acute hemorrhagic pancreatitis we had a disease that was so acute in its onset and so overpowering in its symptomatology that frequently the patient was seen in shock or collapse. In these instances it was with great difficulty that a history was to be obtained. Nevertheless, the intensity of onset, pain, shock, collapse, and a peculiar abdominal lividity all pointed to pancreatitis. Should the patient survive, he would say that he had had a most severe abdominal pain and mayhap backache, that he might have had a previous mild attack, or gallstone attack, etc.

Dr. Herman E. Hayd of Buffalo, N. Y., said that perhaps the most important of all signs and symptoms of gall-bladder disease and ulcer was the anamnesis. If men would spend more time in getting a careful history of their patients they would make fewer mistakes. He did not believe that so many of the mistakes that were made were the result of ignorance but of carelessness. One of the strong points the essayist brought out was that a patient never got an acute pain in ulcer of the stomach or duodenum until the ulcer had encroached upon the peritoneal wall. Just as soon as there was a tendency to erosion of the peritoneum and a possible perforation did we get an acute agonizing pain such as was characteristic of gallstone colic.

Dr. Hugo O. Pantzer of Indianapolis said he had been delighted with the excellent digest of symptoms and signs presented by the essayist in these cases of gall-bladder disease. With the present acceptance of bacteriemic disease, the exanthemata and what not, we were too restricted in our clinical conceptions. Take the matter of smallpox or any of the exanthematous diseases, we were content with knowing the eruption, making the diagnosis, giving routine treatment, and passing away. If in these cases physicians were to look more thoroughly for the localized effect of bacteriemic disease they would find early symptoms pointing to these cases. Having bacteriemic disease of severity, the physician would at once think that these patients might have gall-bladder disease.

The Prevention of the Recurrence of Symptoms Following Operations for Gallstones.—Dr. Julius H. Jacobson of Toledo, Ohio, formulated the following conclusions: "(1) Recurrence of symptoms following gallstone operations are more frequent than is generally supposed to be the case. (2) Reformation of stones after cholecystotomy occurs from retention of infected contents, rather than from leaving gallstones behind at the primary operation. (3) Routine gallstone operations should be made more thorough and complete by the use of adequate incision, by cholecystectomy and by accurate exploration of the ducts. (4) When the common duct shows marked dilatation it should be opened and explored and special attention should be given to the terminal portion of the duct for the detection of calculi and constrictions. (5) The detached gall-bladder from its bed on the liver, acts as an efficient tractor, and greatly aids in making the exploration of the ducts complete."

Cesarean Section.—Dr. Abraham J. Rongy of New York City said that his experience with this operation consisted of 109 cases, 8 of which ended fatally. That he had always been very conservative in choosing the abdominal route for the delivery of a living child could be judged by the fact that during a period of 12 years he had seen approximately 1,500 cases in labor, in consultation with other physicians, all of them presenting some form of dystocia which made the attending phy-

sician anxious, and that out of this great number he only resorted to cesarean section 82 times. Cesarean section had no place in eclampsia when nature had already commenced to do its work, that is, when labor had already set in. In such cases large doses of morphine were the best form of treatment. He still held that cesarean section had no place in the pre-eclamptic stage. In such cases one always had time to induce labor, and the results were usually very satisfactory. The indications and contraindications for cesarean section must be carefully considered. Only one who was well trained in obstetrics had a right to decide upon this operation.

A Study of Various Cases of Pregnancy Toxemia.—Dr. GEORGE CLARK MOSHER of Kansas City, Mo., described the following technique which involved least shock: (1) Preliminary dilatation gradually by Hegar's dilators up to No. 20. (2) Voorhees' bag No. 4, if at term, introduced by Reed's method—cigarette roll held by Péan's forceps. Lavage of sodium bicarbonate, 2 per cent. after uterus was emptied. Cases of the fulminating type—long hard cervix (in which no vaginal examination had been done) were best treated by classical cesarean section. When after contamination by frequent digital examination, infection was almost surely to be expected, a Porro or other hysterectomy should be done in the interest of the mother. A woman without a uterus was better than an anatomical specimen. The results in the series of cases from which these conclusions were drawn showing 95 per cent. recoveries of mothers, 85 per cent. of the children at term—at least warranted the belief that, since Tweedy's tables showed maternal mortality of 18; DeLee, 20; Williams, 25; Cragin, 28; N. Y. Lying-In, 30; the average American, 38; the Royal Maternity of Edinburgh, 66 (these figures being from DeLee's Year Book, 1918), his results were far above the average or else his cases had been less toxic than those encountered elsewhere, which was not likely to have been the case. From his own experience and from that of other observers, including a most interesting report just received from Dr. Ben Meyers, who did a large obstetric work in Alaska, and who found that in the last year, an unusually cold wet season, 12 per cent. of his cases suffered from toxemia—the conclusion was drawn that the weather did at least aggravate the tendency to this condition. As there was such a close relation between the toxemia and the nervous system, was it not also fair to ascribe to the war an incidental effect as a causative factor?

Accidental Removal of Intestines Through the Vaginal Vault.—Dr. EDWARD J. ILL of Newark, N. J., thought as a result of this study and observation, the following points seemed important: (1) Any portion of the bowel could be pulled away by traction with a forceps through a rent in the uterus or vagina. (2) The point of separation would be the junction of the bowel with the mesentery. (3) In some subjects the separation would be extraperitoneal in a large measure. (4) The mesentery could not be pulled away from its origin at the spine or elsewhere. He had reported this because of the medicolegal aspect and that it might form a guide for others. This sort of case would naturally come under observation.

Report of a Case of Pancreatic Cyst in Association with Tuberculous Kidney and Intestinal Complications.—Dr. J. E. SADLIER of Poughkeepsie, N. Y., said that his object in reporting this case was largely for the purpose of demonstrating the number of varied and serious conditions that might exist in one who had considered herself in good health. It was true that pancreatic cysts were rare—this being the very first one it had been his privilege to see—but in this case: (1) he had a patient with acute intestinal obstructive symptoms, which, unquestionably, resulted in a natural anastomosis between the ileum and the transverse colon, thereby overcoming the obstructive symptoms. (2) He had a condition of tuberculous nephritis, with extensive perinephritic infection—operation for which resulted in recovery from tuberculous condition—and also the unfortunate establishment of a colonic fistula in the lumbar region. (3) He had the discovery (and treatment) of the pancreatic cyst—a complex condition which required a great deal of careful thought, study, and work, in order, finally, to bring the patient to her present condition of good health.

Recognition and Management of Labor Injuries.—Dr. ARTHUR J. SKEEL of Cleveland, Ohio, said that the use of gas had done much to make possible more careful work. The production of gas analgesia, or of anesthesia if needed, involved very little discomfort to the patient, and rendered the whole procedure simple. The author wished to emphasize four points: (1) Limiting or entirely avoiding vaginal examinations during labor was a routine preliminary part of the technique of primary repair of labor injuries. (2) Immediate inspection of the cervix, with primary repair of its injuries, reduced the risk of subinvolution and of uterine displacement. (3) The routine use of buried sutures in the perineum for the repair of second degree lacerations permitted accurate coaptation and restoration of the parts. (4) Perineal lacerations were more surely repaired than was subpubic damage. Therefore, slow delivery and skill in directing the small diameters of the head through the vulvar ring should be sought. Forcing the head against the pubic arch produced more damage than it prevented.

Vertigo of the Menopause.—Dr. K. I. SANES of Pittsburgh said that in most of his patients the vertigo was of the objective type, *i.e.* they experienced a sense of rotation around them of the visible or palpable environments. In some of them the vertigo was of a subjective type, *i.e.* a sensation of motion of the body itself. A few of his patients described the vertigo as a sort of swimming movement, a feeling of being intoxicated, an extremely embarrassing condition (the pseudo-narcotism of Tilt). Vertigo was seldom the only prominent menopause symptom; it was almost always accompanied by such disturbances as hot and cold flashes, cold perspiration, palpitation, blurred vision, flickering before the eyes, headache, nausea, tinnitus, etc. The relation of vertigo to climacteric functional hypertension was of interest, and it was claimed by some that it was responsible for the menopause vertigo. Excluding as far as possible the cases of organic hypertension (cardiovascular and renal) he found 102 cases with vertigo that had their blood pressure specified on their records, and of them only 45 or 46 per cent. had their blood pressure above 150 and only 20, or 30 per cent above 160. The severity of vertigo, of course, varied. In most of his cases the vertigo was only slight, just a mild dizziness, in others again so severe that they feared walking by themselves on streets on account of the frequent falls and even loss of consciousness during the attacks of vertigo. What was the treatment for the climacteric vertigo? Before treatment was decided upon one must make sure that he dealt with a case of climacteric vertigo. Such pathological conditions as lesions of the internal ear or of any other part of the balance mechanism, such diseases as cardiovascular renal and ocular, especially muscular imbalance of eyes, must be excluded. If the case could definitely be diagnosed as one of climacteric vertigo, the treatment to be outlined must be that of the menopause in general. As the metabolism was always below par at the menopause, the nutrition and elimination of the patient must be looked after and, as the insufficiency or absence of the ovarian internal secretion was the underlying cause of the symptoms, ovarian organotherapy was logically indicated. In the treatment of his menopause cases he had been using a preparation, each grain of which represented a grain of the fresh ovarian substance, in doses of 5 grains, 2 to 4 times a day. He rarely found any particular advantage in using larger doses. When this dose failed, he only occasionally obtained better results from larger doses. The results that he obtained from the ovarian substance in the menopause, as shown in his records, were about 37 per cent. improvement, and about 25 per cent. complete control. In some cases relief from vertigo preceded, in others followed, and in others again accompanied the relief from the rest of the menopause symptoms. The length of time the ovarian substance was used by the patients was variable, some used it just a month or so, others for many months, and one patient had used it for three years before the final cessation of the annoying symptoms.

Sarcoma of the Left Ovary in a Child Twenty-three Months Old.—Dr. HERMAN E. HAYD of Buffalo said he had removed a small round cell sarcoma of the right ovary, about the size of a goose egg, from a baby

twenty-three months old. The child was running a temperature of 101°, was peevish and irritable, and had lost considerable flesh; it had been sick about ten days, was cutting its eye teeth, and had some bronchitic sounds in the chest and with areas of bronchopneumonia in both lungs. The liver dullness was much increased. The bowels and kidneys were functioning satisfactorily. In the lower right quadrant could be felt a large movable smooth tumor, not painful to the touch. The child was taking milk and liquid nourishment freely, so it seemed best to treat the symptoms, irrespective of the abdominal condition. In the course of four or five days the temperature became normal and the child's condition improved so much that the mother was told to take the child into the country and to return in a few weeks or earlier, if its condition did not continue to improve. When the child returned, she had a temperature of 100°, looked sick, and was again fretful and irritable. She was prepared immediately for an operation, was given ether and through a central incision, this tumor, which was free in the abdomen was removed, with the right tube attached to it. The appendix was long and curled upon itself and it was also removed. The uterus and the left tube and ovary were normal. Quite a little bloody fluid ran away when the abdomen was opened. The liver was very much enlarged and filled with nodular masses. The child suffered but little shock and made an uneventful surgical recovery and left the hospital on the thirteenth day. She died, however, at the end of the fifth week, no doubt, from exhaustion with acute liver and perhaps general sarcomatosis.

The Heart of a Pregnant Woman.—Dr. LOUIS BURCKHARDT of Indianapolis said that the menstrual disturbances, the aversion to physical exercise, and the vasomotor symptoms would help us greatly to single out suspicious cases of this nature, but to depend on marked objective changes in the heart and the general system would cause us to lose valuable time. If a heart affection had progressed to a point where drastic measures were unavoidable, irreparable damage had been inflicted on mother and fetus. Under drastic measures, he included prolonged and absolute rest in bed, the use of opiates and of large doses of digitalis; they all must interfere with a normal metabolism, so essential in this condition. The pregnancy in all but the severest cases must be carried to term, for the interruption of pregnancy offered as many chances of a cardiac breakdown as a normal well conducted delivery—excepting an abortion induced before the formation of the placenta had begun. If a patient with a well compensated heart lesion presented herself for our prenatal care we must impress upon her mind the necessity of preservation of energy. Saving alone did not suffice, but working up of new vital forces was needed —not rest alone, but rest and exercise. He demanded regular exercises and careful attention to elimination in every normal case; we must control both of them most minutely in heart cases. The blood pressure readings would assist us greatly in controlling our patient's work. Between the 34th and 35th week of pregnancy daily observations would be necessary in order to determine the proper time of interference. During this period such patients were best strictly confined to bed. As soon as settling had occurred a considerable amelioration of symptoms was frequently observed and the patient might be given more liberty of action.

Do Not Sterilize Women When Operating for Tuberculous Peritonitis.—Dr. J. HENRY CARSTENS of Detroit stated that there were thousands of tuberculous nodules left in the abdomen after operation for tuberculous peritonitis which were absorbed and disappeared; hence physicians had a right to believe that the few nodules that were left on the tubes and ovaries would also disappear after the abdomen was opened with or without irrigation or drainage. His conclusions were: The thousands of tubercles on the peritoneum were, as a rule, absorbed and disappeared after laparotomy; there was no use in removing the tubes if they were only affected by tubercles; and finally many of the women were young and unmarried, and should not be needlessly sterilized.

Problems of Ureteral Surgery in Gynecology.—Dr. GEORGE VAN AMBER BROWN of Detroit drew the following conclusions: (1) The problem of transplantation of the ureter is often puzzling. (2) In hysterectomy for malignancy of the cervix, one should always isolate the ureters early. (3) In closure of the ureter one can never tell the destiny of the kidney. (4) *X*-ray and urinary findings are probably the greatest source of error. (5) In urology the solution of choice, opaque to the roentgen ray, is one either of sodium or potassium iodide. (6) The destiny of a kidney whose ureter has been tied cannot be easily foretold. (7) No form of operation is ever done until as complete an investigation as possible of both sides has been made."

Intestinal Actinomycosis.—Dr. JOHN W. KEEFE of Providence, R. I., said that actinomycosis of the digestive tract practically never occurred in the stomach or small intestine, possibly because of the acid contents of the stomach and the fluid secretions found in the small intestine being less irritating to its mucous lining. An acute or chronic inflammation of the appendix might open the door for the entrance of the actinomycotic organism. In general, it might be stated that actinomycosis was practically never carried by the lymphatics and but rarely by the blood stream. The method of extension was by continuity of tissue. Thus it was that general actinomycosis, unlike tuberculosis and blastomycosis, was extremely rare. Many of the abdominal organs might become involved with the disease, as extension of the process usually took place through retroperitoneal tissues, sometimes destroying muscular and even body structures. The early stages of actinomycosis were generally overlooked. A firm swelling, painless on pressure, occupying either the right or left inguinal regions, usually the right, was the sign most frequently found in cases of intestinal actinomycosis. The surgical measures to combat the disease consisted of, in some cases, excision, in others, incision and curetting of diseased tissues together with the use of antiseptics and the maintenance of free drainage. Injections of four per cent. formalin solution had been employed with success. Vaccines and serums had been found of value only in a few reported cases. The *x*-ray had not shown any marked beneficial effect. In a few instances radium had been given with marked immediate results. Large doses of potassium iodide, 90 grains three times a day, had been given with success in many cases. Some authors had been so favorably impressed as to assert that it was a specific in this disease. The marked efficacy claimed for this drug was readily explained by the fact that it promoted the absorption of granulation tissue, acting in very much the same manner as in the case of granulomata of tertiary syphilis.

The Rôle of Congenital Colonic Membranes as a Causative Factor in Disease.—Dr. J. P. RUNYAN of Little Rock, Ark., said that colectomy was a radical operation for the relief of intestinal stasis, and in the skilled hands of Lane might be fairly safe, but it had always appeared to him unjustifiable, provided a simpler and a safer operation could be devised. No matter what we might think of the advisability or inadvisability of doing colectomy for its relief, we were doubtless agreed that intestinal stasis was a menace to good health, and that we should endeavor to ascertain the underlying cause and, if possible, correct it. Some patients suffered to such a slight degree that it was questionable whether they should be subjected to operation, while others were so miserable that even colectomy, with its high mortality, might be preferable if we did not have just as effective treatment without its dangers to offer. Acting upon the hypothesis that intestinal stasis was due to colonic membrane formation, the result of imperfect embryological development, which membrane caused more or less angulation of the bowel, he began dividing or removing this membrane, after the manner of Jabez N. Jackson, with most gratifying results. He submitted it as a splendid, safe, and sane substitute for colectomy in the treatment of intestinal stasis, and an operation devoid of mortality and most satisfactory in its results.

Dr. WILLIAM SEAMAN BAINBRIDGE of New York City said it would be unfortunate indeed if it should go out that stasis was not constipation, and constipation was not stasis, and colectomy was not done for the treatment of it by Sir Arbuthnot Lane. Constipation was a symptom just as diarrhea was a symptom. The worst

kind of cases of stasis were those in which the condition was accompanied frequently with diarrhea. The frequency of the number of stools did not mean that the putrifying and noxious material was not there. The retained stool was being absorbed. There was an overflow of retention in the bowel just as there was overflow of retention in the bladder. This point Lane had emphasized repeatedly, and the worst cases of stasis were of that type. When the intestinal canal was dammed, the body as a whole or in part could not take care of the added amount of poisoning with such retention involved. As to treatment, to say that Mr. Lane or any of those that followed him advocated colectomy for stasis was so radical that it did harm. Lane put himself on record in regard to this in 1901 when he said that nine-tenths of the patients with stasis ought never to see a surgeon.

Dr. JAMES E. DAVIS of Detroit said that the body in its development usually followed the law that function determined anatomical form. In cases in which there was some arrest in embryonic development, interference with normal function did not necessarily occur. He had seen instances of this over and over again. Why this was so it was impossible to determine in every instance; but there were a certain number of cases where the arrested anatomical form did interfere definitely. Within the past year he had had the opportunity of doing an autopsy which he thought illustrated this point very beautifully. A child of six weeks died apparently of symptoms of inanition. The autopsy findings revealed this very interesting condition: The right lobe of the liver appeared displaced well down into the pelvis; in fact, it could not be a true displacement; it seemed to be a development. The gall-bladder was in a right-angled position with the mid-axis of the bowel. The lower border of the right lobe of the liver was down in the lowermost part of the pelvis. Through the right hernial ring the cecum and appendix were herniated. The child gave this symptomatology: for the first four days after birth there was no trouble whatsoever, then there began a train of gastrointestinal disturbances, and a little later metabolic disturbances were found. The terminal picture was that of ordinary inanition. In his judgment this abnormality of position was the etiological factor of the gastrointestinal and metabolic disturbances.

Dr. GORDON K. DICKINSON of Jersey City said that in the *Annals of Surgery* for June, 1918, there was a very interesting article on the anatomy and embryology of this subject, and it looked as though the theory advanced by the author was correct. The observations were based on embryological researches and the literature, and the position was taken that all of these bands that were observed and called Jackson's membrane and Lane's kink were embryonal and could be traced back to a very early period of fetal life.

Dr. HUGO O. PANTZER of Indianapolis was pleased to see that surgeons were becoming more and more harmonious in their views regarding this subject. In time they would know more about the symptomatology of the disease and go more specifically after it. These conditions were often associated with a narrow costal angle, with visceroptosis, congenital defects, and so on. Dr. Runyan did not say anything about the narrow costal angle. By percussion one could tell whether the cecum was over the pelvic brim or not; indeed, one could tell by auscultation and percussion a good deal about the abdominal contents.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Annual Meeting, Held in Philadelphia, September 24, 25 and 26, 1918.

(*Concluded from page* 922.)

SECTION ON MEDICINE.

Essential Hypertension.—Dr. HERMAN O. MOSENTHAL of Baltimore in this paper referred to the importance of the recognition of this disease, which so far was characterized by the presence of only one symptom—hypertension. There was known no pathological physiology of the organism bringing about hypertension. It was said to exist in a great number of individuals and usually resulted in severe lesions of the heart, brain, or kidney, causing death. The diagnosis could be made with certainty only when the tests for renal function were available. The most intricate questions in metabolism were involved in treatment. Thus far more theory than fact had been adhered to in management. Mental and physical rest constituted the main elements in treatment. A diet regulating quantity rather than quality was of first importance in food control. The disease demonstrated the value of yearly prophylactic examinations for apparently normal individuals. Attention to hygienic instructions might often prolong life.

Dr. JAMES M. ANDERS of Philadelphia emphasized the great importance of the recognition of essential hypertension. In his opinion the condition was by no means as frequent as indicated by certain writers. Cases had not been excluded in which some cause of hypertension might have been revealed by further investigation. The tests for renal function were necessary in diagnosis. Such tests showed that many cases of apparent essential hypertension could not be so regarded. Cases of persistent hypertension in middle aged men in active business given somewhat to excess in eating, and in the use of alcohol and tobacco, he had found yield to treatment, prolonged rest, and correction of the habits of the patient. These were not instances of essential hypertension.

Dr. ROSS V. PATTERSON of Philadelphia called attention to the form of hypertension under discussion, which must be distinguished from that due to renal sclerosis, in which the hypertension was the primary change and the changes in arteries and kidney were secondary.

Dr. FRANCIS ASHLEY FAUGHT of Philadelphia regarded the renal function test as of very little value, stating that it did not differentiate between a temporary congestion of the kidney and chronic kidney disease. It was his belief that cases of essential arterial hypertension did exist, probably had a cause, that the cause was toxic, and that if such cases did not exist for too long a time they were amenable to relief and cure.

Dr. L. V. HAMMAN of Baltimore said that his reason for distinguishing between essential hypertension associated with renal disease was mainly of prognostic value. He felt that physicians often alarmed patients by telling them that their blood pressure was high. Instances could be noted of patients with a blood pressure of over 200 who had been able to do a normal amount of work for a number of years. The main difference was that the nephritic cases did not last long. Renal functional tests were of the greatest value in the differentiation of the two forms.

The Blood Pressure Question from the Standpoint of the General Practitioner.—Dr. H. A. HARE of Philadelphia emphasized the fact that the result of a blood pressure examination should be taken only as a part of the picture, of no greater importance, if as great, as other parts. A moderately high pressure with a low specific gravity of the urine and many hyaline casts was of far more importance than a very high pressure with a urine practically free of casts. Too much stress, he believed, was placed upon one blood pressure estimation. High estimations made in the office would be far above those taken with the patient at home in bed or in a chair, thus giving an erroneous view of the constant pressure. The practice of estimating the systolic pressure without the diastolic was to be condemned. A pressure above normal might be present for years without giving trouble; a pressure below normal might cause disaster in a few hours. The diastolic pressure subtracted from the systolic gave an idea of the actual cardiac power. He drew attention to the fact that as a man grew older he established what Dr. Hare had termed a "pathological norm," a rising pressure, systolic and diastolic, being essential to his normal existence. Such pressure must not be forced to the theoretically normal level for a man of thirty years. The endeavor should be to reduce the systolic and diastolic pressure sufficiently to relieve stress, and to increase the difference between the systolic and diastolic pressures. In such cases electric cabinet baths, massage, and the alteratives were, as a rule, of more value than the nitrites.

Blood Pressure as a Prognostic Factor.—Dr. R. Max Goepp of Philadelphia regarded blood pressure as more useful in long range prognosis than as an index of immediate developments. Statistics showed hypertension, regardless of cause, to have an unfavorable effect on longevity. "Simple" hypertension, so called, he said, belonged either to the group of early interstitial nephritis or to that of simple arteriosclerosis. Diastolic pressure was regarded as of more importance in prognosis of acute infections than of chronic diseases.

Dr. Francis Ashley Faught of Philadelphia was gratified with Dr. Goepp's emphasis upon the fact that the greatest value in the use of the blood pressure test was derived from the use of certain known ratios and formulas and not from the actual figures obtained by the systolic and diastolic study.

Dr. John A. Lichty of Pittsburgh believed that in ten years essential hypertensions would have ceased to be regarded as a clinical entity. This might be paralleled in the matter of hyperchlorhydria, which twenty years ago was called a disease. Very few of such conditions had been observed since the effect of gall-bladder, appendical, and other conditions upon the gastric secretion had been known. He regarded hypertension as a manifestation of disease or physiological disturbance in an organ which would sometime be understood. He asked Dr. Goepp's interpretation of a constantly low blood pressure.

Dr. Irwin J. Moyer of Pittsburgh believed that the digestive organs played an important rôle not sufficiently dwelt upon in hypertension.

Dr. Goepp, in closing, said that a blood pressure of 100 should not be considered low; large, heavy men were frequently observed with a systolic pressure below 100 and the diastolic 70. The importance of blood pressure, he felt, was tremendously exaggerated and this tendency should be combated by the physician.

The Results of Tests for Food Protein Sensitiveness in a Small Group of Asthmatics.—Dr. Alexander Sterling of Philadelphia gave a review of the clinical pathology of asthma. The reactions of twelve patients were tested with twenty-five different food proteins. There was a positive reaction in only one. In the presence of positive reactions, exclusion in diet and desensitization were indicated. Fifty per cent. of the asthmatics were benefited by subcutaneous injections of gradually increasing doses of foreign vegetable proteins.

Dr. Gordon J. Saxon of Philadelphia referred to the transmission of certain of the asthmatic stigmata from generation to generation, and cited an illustrative case in which the mother, grandmother, and great-grandmother had been victims of hay fever.

Third Day—Thursday, September 26.

Treatment of Syphilis of the Central Nervous System.—Dr. T. P. Tredway of Erie emphasized the importance of early recognition of involvement of the central nervous system and the selection of cases mentioned the following as the methods in common use in the intraspinal injection of arsphenamine and mercury: (1) Autoarsphenamized serum, (2) Arsphenamine in small quantities added to serum, (3) Mercurialized serum, (4) Arsphenamine in small quantities added directly to the fluid. The author's best results had been obtained by the last mentioned method. In paretics he believed that a prolonged remission was the best that could be accomplished. In tabes dorsalis he had seen cases in which, clinically, progression had been retarded for three years; best results followed the combination of general and intraspinal treatment.

Observations of the Intraspinal Autoarsphenamized Serum Treatment of Cerebrospinal Syphilis.—Dr. B. A. Thomas of Philadelphia in this study did not claim that arsphenamine therapy removed the possible necessity of institutional care, but believed that the accessory employment of intraspinal treatment accelerated restoration of the spinal fluid to normal. Intraspinal treatment by autoarsphenamized or arsphenamized autoarsphenamized serum injections should supplement intensive intravenous therapy when necessary. Treatment in qualified cases should be continued until the spinal fluid and the blood findings were negative, except globulins which might continue positive in many cases irrespective of the amount of treatment.

Dr. Loraine L. Schwartz of Pittsburgh believed that unless the necessity of routine lumbar puncture in all cases of syphilis was universally recognized by the medical profession there would be as many posterior sclerosis tabetics, paretics, and cerebrospinal cases in twenty years as at present. Opportunities for better work rested primarily with the physician seeing the patient during the first six months of the infection. Upon the slightest sign of central nervous involvement it was his custom to have the spinal cord explored and he believed that in this way the patient was saved many doses of salvarsan.

Dr. Jay F. Schamberg of Philadelphia emphasized the responsibility of the medical profession regarding the treatment of syphilis. Especially valuable in his opinion was the colloidal gold test in warning of impending changes in the nervous system. It was to be realized that the blood Wassermann did not indicate the changes taking place in the central nervous system. Were the early spinal fluid changes detected and persistent and scientific treatment instituted he believed that tabes and paresis could be banished. A striking instance of syphilis was cited in which marked relief was obtained in thirty-six hours after an intraspinal injection of arsphenamine.

Dr. Alfred Gordon of Philadelphia referred to his experience with several hundred cases of neurosyphilis in some of which brilliant results attended the first or second administration of autoneosalvarsanized serum. In one case the intraspinal treatment was followed by immediate relief of pain.

Dr. Paul G. Weston of Warren referred to the grouping of paretics in their hospital, each group being given a different form of treatment and one additional group receiving no anti-syphilitic treatment. Practically no difference in the average length of life between the treated and untreated was found, and at autopsy the same changes in the brains were found in these two classes. He said that ten or twenty years would be needed for the testing of the problems presented.

Dr. John A. Lichty of Pittsburgh referred to the statement appearing in the *Survey* that the annual expense to the State of New York for the syphilitic was about five million dollars. Such an outlay multiplied by the number of the other States could at the present time be advantageously applied to the building of more ships. In his opinion were the subject of syphilis managed by the State Board of Health, the Committee on Medical Education and State Licensure, and the State Board of Charities somewhat as tuberculosis is supervised, a very satisfactory degree of success would be obtained.

Dr. Thomas, in closing, agreed with Dr. Weston in his estimate of the treatment of paresis. He had obtained no good results and one case had been made worse. The gold test had been of no value in his work.

The Application of the Principles of Advanced Psychiatry.—Dr. J. Allen Jackson of Philadelphia stated that in communities with a population of over 500,000 service would best be obtained through a municipal bureau of mental hygiene under the supervision of a trained psychiatrist with subordinate district supervision. Definite psychiatric centers under the direction of an alienist assisted by a trained field worker should be established in the districts. Public education should here be encouraged. Early care and treatment with assignment to proper institutions could be thus carried out. The alienist in charge of the psychiatric center should bear the same relation to the custodial institution as the medical inspector of the Bureau of Health to the Hospital for Contagious Diseases. While the immediate effect of such a bureau would be a temporary increase of custodial patients there would ultimately be an increased recovery rate. By such measures the propagation of the mentally unfit would be checked and the cost to municipality and State would be eliminated.

Dr. John A. Lichty of Pittsburgh was in hearty accord with the method of organization suggested by Dr. Jackson. The scheme in his opinion represented economy and efficiency, the saving of lives and the bringing back to health of many now submerged.

Dr. S. Solis-Cohen of Philadelphia strongly endorsed the scheme outlined by Dr. Jackson. He wished

that the same method might supplant the present mode of dealing with the subject of tuberculosis.

Dr. Frank Woodbury of Philadelphia was in strong sympathy with the paper presented by Dr. Jackson. In the analogy of tuberculosis and insanity in the matter of management the important distinction was to be made of knowledge by the profession of the cause in the former. In a case of insanity the nature of the disease which produced the mental disorder was to be determined. It was wrong to disqualify a man for life by commitment to an insane hospital were this not necessary for his welfare and the protection of society. To diffuse among the general profession a better knowledge of mental disease was stated to be the duty of psychiatry.

Dr. E. E. Mayer of Pittsburgh would add to Dr. Jackson's diagram the suggestion that hygiene should deal with the social problems of the community as well as with the mental. Until there was in operation a plan by which social and vocational agencies cooperated with the medical profession he feared the largest good would not be accomplished.

Professor Norbert J. Melville of Philadelphia stated that the Mental Hygiene Committee of the Public Charities Association was prepared to cooperate in any community with physicians who were ready to direct such cooperation. The Committee was already working through welfare agencies to convince social workers that they should consult the specialist for direction in social psychiatry; also pointing out the desirability of their staff taking courses in the principles of social psychiatry. It was the thought of the Committee that with the organization of volunteer workers, the State might eventually take over the work.

Prognosis of Cases of Intestinal Perforation in Typhoid Fever Without Operation.—Dr. C. W. Eisenhower of York urged that the physician watch closely for complications in typhoid fever and call the surgeon immediately upon the suspicion of perforation. The experience of the general practitioner was that recoveries from intestinal perforation in typhoid fever without operation were more frequent than indicated in the textbooks. In some instances, evidence had been found of a local protective plastic peritonitis preventing escape of bowel contents, resulting in recovery. The prognosis of intestinal perforation was regarded as too grave to warrant departure from the accepted treatment of prompt surgical intervention.

Dr. S. Solis-Cohen of Philadelphia, though agreeing almost entirely with Dr. Eisenhower, referred to the teaching of J. M. Da Costa and Alonzo Clark in preoperative days, that about one case in four of typhoid perforation might be expected to recover. Their plan of treatment had been the administration of opium to the point almost of stupefaction, with the administration of minimal quantities of fluid nourishment every three or four hours. Dr. Cohen had personally had similar results. He would, however, with Dr. Eisenhower, emphasize the importance of as early an operation as possible.

Dr. David S. Funk of Harrisburg said that in a remote rural district he would give in a case of typhoid fever with perforation a prognosis barely distinguishable from crepe on the door. He had, however, seen one typical case of perforation recover in a woman too ill for operation.

Dr. George E. Holtzapple of York was inclined to believe that more cases recovered without operation than indicated by some writers of textbooks. While operation was the proper treatment for perforation, if for any reason operation could not be done there should be no relaxation of the efforts of the physician.

Dr. James I. Johnston of Pittsburgh had seen cases of typhoid perforation in which the patient had refused operation, and which had recovered. One case was cited in which, upon section, it was found that the omentum had fallen against the perforation, sealing it over. No further operative work was done, and recovery occurred.

Pellagra.—Dr. L. L. Schwartz of Pittsburgh mentioned the three theories given concerning pellagra—the deficiency, the maize, and the parasitic, the latter being the most widely accepted at present. While the usual duration of the chronic form of the disease was from five to ten years, in America death during the first or second summer was common. The cardinal symptoms, he said, were often indicated by the alliterative formula—dermatitis, diarrhea, and depression. The first essential in treatment was removal of the patient from the surroundings in which he had acquired the disease, accompanied with the institution of a liberal mixed diet. Arsenic was the one drug of apparent value, and the forms in which it seemed to be most useful were salvarsan intravenously, or sodium cacodylate given intramuscularly. One case was reported which had been referred to the author's service in the Mercy Hospital by Dr. Clement R. Jones of Pittsburgh.

Dr. James I. Johnston of Pittsburgh had seen this case, and at first it suggested to him the possibility of typhoid fever, with incidental skin eruption; syphilis was also thought of. Upon further study it was diagnosed as pellagra, and this was corroborated at autopsy.

Dr. John G. Burke of Pittsburgh referred to the profound toxemia present in the case, for which no cause could be found, and thought it a peculiar circumstance that one case should be observed without the occurrence of others.

Dr. Paul G. Weston of Warren referred to Goldberger's experiments, as yet not confirmed, which seemed to show that pellagra was a deficiency disease. He felt that an interesting parallelism existed between a low per-capita cost and the presence of pellagra in institutions for the insane. Some one had recommended that the first step in the treatment of pellagra in an institution should be replacement of those responsible for the disease by persons having a greater interest in the patients than in the per-capita cost. Following this there should be an increase in the animal proteins in the diet. He inclined to the belef that the disease was more prevalent in the Northern States than was generally known.

Dr. Schwartz, in closing, said that the diet of the man whose case had been reported was principally that of the farm life. He believed more cases of pellagra existed in the Northern States than was supposed by the profession, and thought they were often not recognized until the final stages were apparent. The case cited had been claimed by the dermatological, the neurological, and the gastrointestinal men. The three cardinal symptoms had been very prominent. The Wassermann was only faintly positive.

Serum Treatment of Epidemic Cerebrospinal Meningitis.—Dr. John A. Kolmer of Philadelphia referred to the reduced mortality of epidemic cerebrospinal meningitis with the serum treatment by the intraspinal route. The gross mortality of 70 to 90 per cent. among cases not treated with the serum had been lowered to 30 per cent. by the serum treatment. The problem was complicated by the fact that more than one type of meningococcus was capable of producing the disease, and that the microorganisms might be carried and disseminated by convalescents and healthy carriers. It was regarded as highly important to employ a potent polyvalent serum in the treatment of meningococcus infections because at the present time type diagnoses and the employment of monovalent serums were not availment as in the diagnosis and treatment of lobar pneumonia. During epidemics between 1 and 2 per cent. of persons were chronic carriers, constituting the greatest source of danger. With the least clinical suspicion of meningitis the physician should resort to spinal puncture. It was stated that Flexner regarded the microorganisms as infecting the meninges by direct extension along the lymphatics of the olfactory nerves, with their occasional presence in the blood stream. Recent studies, particularly by Herrick and Caeslack, indicated that the coccus might be present in the blood more frequently than heretofore thought, and that this "meningococcus sepsis" might produce systemic symptoms. It is Dr. Kolmer's custom to culture the blood routinely at the time of spinal puncture. If after two intraspinal injections of large doses of antiserum no improvement was shown clinically or in the analysis of the cerebrospinal fluid, the author advised that a serum of another manufacturer be substituted, with the hope that it might contain specific antibodies not present in the first. Upon the basis of his experi-

mental results with the influence of fresh normal serum alone and in combination with antimeningitis serum upon viruldent meningococci, Dr. Kolmer believed the method worthy of further trial in improving the results of the serum treatment of meningococcus-meningitis.

Election of Officers.—The annual election resulted as follows: *President,* Dr. Cyrus L. Stevens, Athens; *First Vice-President,* Dr. Wm. Duffield Robinson, Philadelphia; *Secretary,* Dr. W. F. Donaldson, Pittsburgh; *Assistant Secretary,* Dr. C. B. Longenecker, Philadelphia; *treasurer,* Dr. George W. Wagoner, Johnston.

The next place of meeting will be Harrisburg.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

ANATOMY OF THE HUMAN BODY. By HENRY GRAY, F.R.S., and WARREN H. LEWIS, B.S., M.D. Twentieth Edition. 1,396 pages. Illustrated. Price, $7.50 cloth and $9.00 leather. Published by Lea & Febiger, Philadelphia and New York.

Miscellany.

Feeble-Minded Children.—In *Public Health Reports,* May 17, 1918, Dr. Walter Treadway, passed assistant surgeon, U. S. P. H. S., formulates the following conclusions based upon observations on the personality of feeble-minded children in the general population: (1) In addition to certain formal psychological tests the children who grade below certain normal limits, or who show certain unusual traits of character, should be studied by psychiatric methods. (2) Certain constitutional traits occur with sufficient frequency in the mental defectives to warrant their being recognized as types for future study. The following tentative classification is suggested: (a) Those with shut-in tendencies; (b) those with maniac-depressive-like reactions; (c) those allied to the maniac-depressive group; (d) those who show the egoistic and epileptic temperament, and (e) those who show a fatuous temperament. (3) Constitutional traits must be taken into account when making a diagnosis of mental deficiency, or feeble-mindedness as it is more often termed. Future studies in the field may show that they are of practical value in differentiating the mentally defective child from one merely retarded. (4) A knowledge of psychiatry is an important requisite in the diagnosis of feeble-mindedness. This becomes of more importance when it is realized that a close relationship exists between psychic disorders usually regarded as insanity and the higher types of mental deficiency or feeble-mindedness. (5) The recognition of these constitutional traits will permit a better understanding of impure or atypical cases in mental medicine and, furthermore, offer a means of recognizing antisocial traits in mental defectives before society has paid the penalty of their inherent antisocial tendencies. (6) The understanding of these traits permits, early in the career of the feeble-minded, the inauguration of prophylaxis, which may serve to prevent much sorrow and disgrace to their immediate families: First, by segregating certain types in institutions early in life, regardless of the financial status of the family, and second, by replacing through early training vicious tendencies which the feeble-minded child easily adopts and which are not readily overcome when once developed.

Cremation.—From the *Boletino del Departamento de Salubridad Publica* for June 30, we learn that on February 15, 1909, the cremation of human cadavers was initiated at the Dolores cemetery, Mexico City. The total number of cremations to date is now 18,160. In the year 1913 and 1914 cremation was temporarily suspended and since its resumption the average annual number has fallen notably, although the present year will doubtless equal or surpass any of the former years. When Mexico took up cremation she simply re-established a custom of the ancient Aztec population. Dr. Valenzuela, editor of the *Boletino,* gives an account of the funeral ceremonies of these people. Among Old World countries the cremation of the Greeks and Romans was abolished by Christianity and only India has kept up the custom without respite for centuries. In 1876 there occurred a revival of the old custom in Italy.

THE MILDER FORMS OF MANIC-DEPRESSIVE PSYCHOSES AND THE MANIC-DEPRESSIVE CONSTITUTION OR TEMPERAMENT.*

BY B. ONUF (ONUFROWICZ), M.D.,
PARK RIDGE, N. J.

EX-PRESIDENT NEW YORK PSYCHOANALYTICAL SOCIETY, ATTENDING NEUROLOGIST, BARNERT HOSPITAL, PATERSON, N. J.

THE term manic-depressive insanity was introduced by Kraepelin and has found general favor. The purpose was one of simplification and unification. Just as the concept of tuberculosis was simplified by the recognition that the various anatomical and clinical forms of manifestation of the disease, the desquamative pneumonia of Laennec, the caseous peribronchitis, miliary tuberculosis, caries of the bones, glandular tuberculosis, lupus, etc., had one main source of origin in common, the invasion of the tubercle bacillus, so Kraepelin recognized in the cases of simple mania and melancholia, recurrent mania and melancholia, periodic mania and melancholia, and circular insanity, the latter known in its milder forms as cyclothymia, common binding traits. He showed that the apparently so contrasting manic and melancholic manifestations could so to say go hand in hand, side by side.

That the same individual could show periods of mania, alternating with periods of melancholia and periods of a more or less normal state, had already been demonstrated long before by the existence of circular or cyclic insanity. It was Kraepelin's merit, however, to have shown that the blending of these two opposite conditions in the same person was much more frequent than had been believed before and that it could occur in all sorts of ways, of which the following are the most typical:

Classification of Manic-Depressive Psychoses.—1. Manic, depressive, and normal states may follow each other in regular succession in a typical cycle.—Circular or cyclic insanity, called cyclothymia in the mild form.

2. The normal state may be broken into by manic attacks and by depressive, *i.e.* melancholic attacks at irregular intervals and in irregular succession.—Periodic manic-depressive insanity.

3. Manic attacks interrupt the normal state at various intervals, but they are rarely if ever purely manic; depressive episodes of longer or shorter duration, sometimes only of hours or less, sometimes of days, occur during the manic attack, or the manic attack is ushered in by a depressive forestage.—Periodic or recurrent mania.

4. Depressive or melancholic attacks interrupt the normal state at varying intervals, being again often or usually mixed with or preceded by manic episodes.—Periodic or recurrent melancholia.

5. Only one or two actual *manic* attacks occur in a lifetime, but the manic depressive make-up to be described later is present.

6. Only one or two *depressive* attacks occur in a lifetime, but the manic-depressive make-up exists.

7. All possible other mixtures or combinations are found: A melancholic emotional attitude, for instance, may be associated with verbosity, flight of ideas; or a manic emotional attitude may be associated with a stuporous state.—Manic Stupor.

It is not the purpose of this paper to dwell on the severe forms of mania and melancholia. I shall therefore refer to these briefly, not more than is needed for a general understanding of this subject.

Description of Marked Manic Attack.—Well developed cases of mania are characterized by a feeling of exaltation, of general well-being, increasing to boisterousness, expressing itself by talking, shouting, hollering, laughing, singing, dancing, joking. There is increased sensuality, showing itself in the sexual sphere as an increased sexual desire which is exhibited in undisguised, scandalous, gross advances towards the opposite sex with the use of licentious, indecent language, swearing, etc.

There is a feeling of increased power, with intent to show it by feats of strength and daring, by a defiance to being ruled or checked. Activity is increased in a more and more disordered manner, the more the disease advances, showing itself in destructiveness, tearing up clothing, pulling down of pictures from the walls, of fixtures, of mouldings. They may show the agility of cats, climbing up trees, etc.

The increased activity shows itself also in their speech. They exhibit an increasing verbosity, at times an incessant talk, which like their actions becomes more and more disordered as the disease nears its climax. The thoughts follow each other in quick succession, apparently without any binding links—so-called flight of ideas. Close observation often shows, however, that the binding links are present but are skipped over so rapidly that one has to be very alert in detecting them. The mental associations are superficial, expressing themselves in resemblance of sound, thus giving rise to rhyming, playing on words, or superficial

*Read before the Bergen County Medical Society, June 11, 1918.

grouping and successive enumeration of things, say from color association or in a similar manner. For instance, "red and blue, I do not like you (U), V, X, Y, Z, the man went to sea, see sight, goodnight. The night is black, back, back, back."

Objects just coming into their line of vision or sounds just heard or other sense-impressions of the moment are at once drawn into their talk by a quick allusion—so-called distractibility.

The appetite is increased, and they eat voraciously unless the motor activity becomes so disordered and hurried that they do not find the time to eat. Activity of the bowels also is increased, but stools may become retarded for the same reason.

The sporadic manic attack is often ushered in by a depressive forestage of longer or lesser duration.

Description of Marked Melancholic Attack.—In a melancholic depression the conditions are the opposite of those of the manic in most respects.

In place of the exalted, elated emotional attitude there is deep gloom, discouragement, a feeling of hopelessness. The patients cannot enjoy anything. Everything appears in a distorted, pessimistic light. They are deeply convinced that they can never be happy again, that life has nothing more in store for them, that nothing can be done for them. This and the great anguish connected with it, causing anticipation of some terrible happening, of a frightful impending death, makes them wish to end life by their own hand rather than go through the anticipated ordeal. Thus they attempt and often succeed in committing suicide.

In place of the increased sexuality and cynicism of the manic we see in the melancholic a lessened sexual desire and a feeling of chastity and strict maintenance of decorum—with notable exceptions, however.

The feeling of self-satisfaction of the manic is replaced by feelings of regret, of self-reproach in the melancholic: "I ought to have acted differently. have brought this unhappiness on myself, am being punished by God for my shortcomings or sins," etc.

Instead of the feeling of increased power of the manic, the melancholic patient has a feeling of diffidence, incapacity, inability to accomplish anything. Thinking is painful, an effort, concentration greatly impeded. Thoughts come slowly and recalling things from memory becomes a laborious task. This interference with thinking and recalling is designated as mental retardation and forms a strong contrast with the flight of ideas of the manic, his often remarkable ease of memorial reproduction, especially of old events.

In place of the overactivity and verbosity of the manic we find in the melancholic or depressed patient lessened activity and reticence to the point of so-called melancholic stupor, in which active movement is reduced to a minimum and speech suspended, although in some there is on the contrary an agitation of action and of speech approaching the flight of ideas of manics. The counterpart of this uncommon feature of melancholics is the uncommon arrest of activity in some manics, known as manic stupor, and so far as known to me, first described by Kraepelin.

Appetite is almost invariably diminished in melancholics, often to the point of complete refusal of food, to which result the feeling of unworthiness or the delusion of abject poverty greatly contributes. This is in contrast to the voracity of the manic, if such is not neutralized by his rapid, shifting, disordered activity.

Constipation is the rule, as against the usually free activity of the bowels in manics.

Mild Forms of Manic-Depressive Psychosis.—The mild forms of mania are usually designated as hypomanias, of which the following clinical picture as observed in a Jewish girl of 21 years during her stay at "The Oak" is illustrative:

Case 1.—*Hypomania.*—Patient is mildly elated, showing herself contented and giving unstinted praise to her surroundings. She describes the place, the care, and the meals here as grand. Everybody is lovely to her. She shows a marked activity, but of an ordered manner, yet with frequent shifting and a restlessness of purpose. She takes at once an interest in the patients and wants to take care of them, nevertheless soon losing patience when they obtrude themselves on her.

She writes letters by the dozen, in an elated style mostly of a flirtatious character and with many fabrications made evidently in the spirit of harmless bragadocio. In one of them for instance she writes to a girl friend that she is swimming and motoring, that to-morrow two Princeton chaps are going to take her on a motor ride, that there is "a bunch of game girls" here, all of which statements have no basis of fact, the reference to the patients as a bunch of game girls being irresistibly comical. She invites most of the addressees to visit her, many of them being quite superficial acquaintances. She is bent on having all the letters mailed, secreting some of them in her clothing.

She is so far amiable, good natured, seemingly perfectly amenable to the sanatorium discipline. With all that she has a rather bad influence on a young epileptic female patient, coaching her to pretend that she did not hear when her name was called, having talks with her of an erotic character. She exhibits a marked flirtatiousness towards the male sex expressed also in the numerous letters mentioned, remaining nevertheless in the limits of decency in her conduct toward the male sex. She is stylishly, coquettishly, but neatly dressed. She displays much liking for music both receptively and actively, letting the phonograph play and playing herself on the piano, with preference for lively, dashing, and also trashy music, executing the same in a loud and rather trashy manner, with many mistakes.

The patient is perfectly oriented regarding time, place, and surroundings. Attention is perfect and she is very alert, giving one the impression of one that has to be carefully watched against impulses to run away, conducting of clandestine correspondence, etc., as she would quickly seize any opportunity to elude watchfulness. Her memory is good. She enters other rooms, using articles of clothing and of toilet of other patients and of the supervising staff.

The formal content of her speech is well ordered, showing no tendency to giving way to superficial associations. She gives evidence of intelligence and culture. Sleep and appetite good, bowels regular.

On September 25, 1915, ten days after admission, the following note was taken: "Has become more systematic, more settled in her activities, spending a good deal of her time in embroidery work, although doing the same in a careless, ragfashion manner. Litters the grounds up with torn-up letters. Still writes numerous letters, addressing one of the young men written to as her husband and sweetheart and using other endearing terms, speaking effusively of her affection for him (this man made it very distinctly understood to her folks that he did not want to have any correspondence with her). Writes to another young man in the same manner, except that she does not call him her husband. The letters contain very thinly veiled erotic allusions, speaking for instance of men's admiration of her legs, of the wedding night, etc. In the letters to her family she at times shows discontent,

finds fault with all sorts of things, misrepresenting conditions with the evident intent to arouse her family's sympathy and to be taken home. Four days ago she made an attempt to run away, which was nipped in the bud. Patient eats and sleeps well. Has had only one night of actually poor sleep, owing to disturbance of another patient."

September 27, 1915.—Weight 120 lbs., a gain of 5 lbs. since admission (September 15).

The following case, of which I likewise render only the notes of the mental examination made on her admission to "The Oak" (April 28, 1915) and again six days afterward (May 4), is a good type of hypomania, though differing in some points from Case I. It also concerns a young girl, age 25.

Case II.—Patient shows a mild maniacal exaltation, manifested by marked talkativeness, but without flight of ideas and without tendency to superficial associations. Develops considerable wit, and makes many good, snapshot-like observations and commentaries of character and disposition, all given in a good-humored way, without malice. In a naive way she confesses to a mild erotism, exhibited by her saying that somehow she always thinks of men, that men somehow all fall in love with her. The emotional tone is one of euphoric elation, but with a certain sensitiveness and interrupted by occasional crying spells occurring on slight provocation or without apparent motive. She is perfectly oriented, perfectly willing to cooperate, desirous to get full benefit of the sanatorium treatment, and offering to be occupied to promote this purpose. Patient is intelligent and alert.

May 4, 1915. Is becoming decidedly less talkative and the elation is ceding to a more sensitive, irritable feeling tone, dislikes hearing sad tales and begs to be kept from the patients who are wearying her with them. Is irritated at the alleged heavy walk of one person and at other things not affecting a normal person, thinks the children who are on a visit here walk strangely, as if ordered to do so, and utters a few more slightly paranoid ideas. At a visit of her mother and sister, she expressed herself as fearing to go to bed, being afraid of the writer, etc.

Sleep, pretty fair even the first night, has been constantly improving. Now sleeps almost all night until daylight.

Special Features Observed in Hypomanias.—In discussing the two cases just reported attention is called to the erotic manifestations accompanying the milder forms of maniacal exaltation. This has especially reference to women, and particularly to young girls. The latter are to be carefully watched, but not in a severe manner, as by antagonizing them one is apt to make them discontented and defiant. In that phase they are apt to write love letters to almost anyone, containing gross, thinly veiled sexual allusions in these professions of their loves. They employ all sorts of tricks to have the letters mailed, by dropping them on the street or slipping them over to a passer-by, etc. Their loves, at such times at least, are very polyandric. One does not mind writing to one man calling herself his wife and writing in the same mail to another one, in almost the same vein, saying how happy she would be to have children by him and the like.

It occurs to the writer that many representatives of the "summer girl," of whom we hear so much and read about in the comic papers and magazines as becoming betrothed to another fellow each summer season, the engagement breaking up invariably at the end of the season, may belong to the manic-depressive type. That a manic-depressive enters a matrimonial engagement in a hypomaniacal state to break it again in a depressed state, there is no doubt about.

Of interest is the attitude maintained by actual wives toward their husbands, the change that occurs in their feelings toward them. They often feel so alienated toward them in that phase as to ask for divorce, and at the same time they usually fall in love with some one else. When confined in an institution they are very apt to have runaway impulses, in order to acquire the desired freedom, especially sexual freedom.

Very often masturbatory trends are greatly developed and too serious reprisals to stop them may lead to sexual relations with the opposite sex.

As was indicated in the case first reported, there may be marked moral looseness in women who were formerly of strict morals. The thieving habit, that is, taking things from other people, making often no attempts or very faint attempts to conceal these acts, are not infrequently noticed. Such cases cannot be classed as kleptomanias, as they occur only during the maniacal state.

The nonchalant attitude against reproof is another point worthy of note. Censure of their conduct is apt to glance off like water off a duck's back. This is often in sharp contrast to their former attitude of strict obedience and impressiveness to such reproofs. Very often we observe the so-called *folie raisonnante* tendencies in these cases. They argue their case, give all sorts of plausible motives for their abnormal or unusual actions. Yet their true motives are quite different, entirely morbid, in conformity with their morbid state.

The Physical Changes.—The mental changes above mentioned are often of a rather subtle kind and one who does not know the patients is apt to construe their actions in a way very prejudicial to them. Often, however, marked physical changes accompany the mental ones and they occur especially in the cyclic cases with such regularity at certain phases of the disease that they in themselves become convincing of the pathological nature of their state. These changes concern the weight, the appetite, the bowels, the skin, hair, eyes.

As to the weight, such may offer typical fluctuations, particularly in the cyclic cases, increasing usually toward the abatement of the maniacal symptoms, sometimes also during their gradual development. However, the phase during which the increase of weight takes place varies considerably. In the state of depression the weight usually goes down and differences between maximum and minimum weight may amount to as much as forty or fifty pounds. The appetite, as has already been mentioned under the symptomatology of the severe forms, is usually increased in the manic and lessened in the depressed state. The bowels usually move freely during maniacal exaltation and are constipated in the depressed times.

The skin is apt to be dry, sometimes scaly in the depressed state, moist or at least reacting freely to sudorific influences in the maniacal state.

Differences in the appearance of the hair are sometimes called attention to by the patients themselves. They find their hair of a rather dry, brittle quality and without luster during depression, and soft and pliable in the manic state.

The eyes often strike one by their brilliancy, sometimes even a slight exophthalmus, in the maniacal elation, as contrasted to the dulness and

lusterlessness in the depressed periods. Likewise depressed patients usually are pale, anemic, pasty-looking, whereas in the mild maniacal state they usually have good color.

The *milder forms of depression* of manic-depressive patients differ from the severe ones in the degree of the symptoms, although the one noted in the following case took apparently about a year for its full development, declining gradually after that, but not ending in full recovery until almost 2 years after its onset. It concerns a young man of 30, of more than average intelligence and horizon, who at the time of admission to "The Oak," July 14, 1915, showed the following mental condition:

CASE III.—*Mild Depression.*—Patient on admission appears depressed, diffident, and extremely undecided. Cannot come to a decision as to entering the sanatorium, although having come manifestly prepared for such stay, that is, with a properly packed suitcase. He appeals to both his wife and writer for advice, asks whether it is the only way to get well. With all that he shows marked insight and full willingness to cooperate and ultimately comes to a spontaneous decision to stay.

He shows himself well mannered, courteous, and obliging, gentlemanly, giving, in spite of his depression, the impression of intelligence and of a somewhat larger horizon and sphere than corresponds to his position, which is mostly of a clerical character. He is oriented as to time and place, and shows no gross defects of memory, in spite of the difficulty of recalling things at will.

His attention is on the whole good and in spite of his alleged difficulty of finding words, speech and articulation show no objective disturbance. The formal content of his speech is coherent, devoid of flight of ideas, and he relates his own history in an ordered manner.

His subjective complaints, summarized, are as follows: "Insomnia, a whimsical appetite, nervousness, inability to concentrate, indecision, lack of self-confidence, particularly as to his capacity to do his work properly; retrospective belief that he never had capacity for the work he has been doing for the past years, fear of losing his position, of never being able to fill a position again, difficulty of recalling things at will, difficulty of expressing himself, *i.e.* of finding the proper words. His own account of the development of his depression is so interesting that it was decided to render it in full here below:

Development of the psychosis (Patient's account): At the end of March, 1915, patient began to have uncomfortable feelings, a vague apprehension. He had obtained a responsible managing position in the office where he worked, after having first occupied a more clerical one. The increased responsibilities came on gradually. At the time mentioned, that is, the latter part of March, 1915, he began to fear that he could not fill the place with the increased responsibilities and the needed business capacity implied thereby. He saw everything black, the least things caused him worry, and he began to apprehend that a nephew of his employer, who had come over from Europe and become employed at the office in May, 1914, was going to supplant him. In the retrospective he now thinks the man was too young and too inexperienced in that particular office to fill the place.

He (patient) experienced more and more difficulty in performing the work connected with his position. All tasks seemed so difficult and he envied others that they could work nicely and enjoy their work. Some salesmen whom he formerly considered as greatly inferior to himself in mental capacity, he began to think were better qualified than himself. He commenced to be very restless, had no patience to finish anything begun, wanted to get away from everything in the office.

When a letter arrived that he had to answer, he had to read it again and again, could not put his mind on it, always thinking of other things and getting so confused and disgusted that he had to refer it to someone else to reply. Whenever something came up that required a decision he had to leave it either to his employer or to his manager; he could never make a decision alone, *i.e.* without consulting somebody. Retrospectively, he now thinks that he could have done it.

Another cause of worry was that the manager of the concern, owing to dissensions with the employer, spoke of leaving and patient feared that in that case the business would suffer and might go to ruin altogether and that he would not be able to fill his place as he would have been expected to do in the natural course if said manager did leave. At the same time increasing difficulties arose, owing to the war, of obtaining goods from Austria and Germany. There was consequently good ground for the fear that sales would be less and that the business would greatly suffer. The sales indeed were less than half those of the previous year.

Patient became more and more nervous; he often stayed home till 10 A.M., not being able to make up his mind to go to the office, because he concluded he could not do anything and would be only in the way of the others, retarding their work.

On June 12, he obtained a leave of absence of two weeks, asked for at the suggestion of Dr. Joseph Fraenkel. His employer was very willing that he should have the leave but his manager intimated, patient thinks, that he was to be discharged altogether, telling him to forget everything and saying that perhaps he would not have to come back at all. This and the conduct of his associates, as it appeared to him, gave him the impression that he was looked upon as a discharged man. He thought they looked at him commiseratingly and the manner in which they spoke to him confirmed his impression and he only thought, "Why don't they tell me that I am discharged?" He then went on his leave to Sea Cliff, L. I. After a week of the two weeks allowed to him, in accordance with a prearranged understanding, he would come back to the office for a day but found that he could do even less than before. His employer then told him to stay over the fourth of July but to come back for a day on June 28 to close up the books for the half year. Patient then returned to Sea Cliff. In the meantime his employer fell ill and this affected him deeply and when he came back on June 28 to help close up the books, as arranged, he could not do anything. He became so depressed that he did not want to go out or to dress. He was at the time advised by Dr. J. Fraenkel to go to "The Oak," but being unable to make up his mind to do this, went back to Sea Cliff instead.

Sleep became impaired the first part of April, becoming gradually worse. He lay awake a good part of the night and when he did fall asleep, the least noise woke him up; he slept only when so exhausted that he could not keep his eyes open. Previously his sleep had been very good, averaging from 7 to 8 hours. The appetite was not so much affected, yet at times, especially lately, he did not care to eat. He never had been a great eater. Bowels remained regular. Ever since April he had the feeling at times as if everyone looked at him and thought he was sick. Now this idea appears ridiculous to him. Sexually he did not notice any change except that for the last month or so sexual desire appeared increased, at least the desire appeared to exist to get something to divert his thoughts.

Patient states that his wife told him she had noticed a change in him as far back as August and September, 1914, that is at the time of the outbreak of the European War. She found him becoming more irritable than previously—he always having had a somewhat hasty temper—and reticent. She said that patient at the time expressed the fear that the importing business in which he was engaged as an employee would be unfavorably affected by the war and that his fear, although not materializing at the time, may have reflected itself on him even then. Patient himself was not aware of the change observed by his wife but it occurs to him now that even in January, 1915, his mind was not as active as before, that he sometimes could not express himself as readily as previously, could not find the proper words, could not recall things as easily, emphasizing that his memory had been a particularly good one. He states in illustration that when he was shown in May, 1915, a contract that he had signed in January of the same year, he was highly surprised to find that he really had signed it, having no recollection of this fact even now.

Physical examination showed patient to be a man of fine, almost athletic muscular development. Special features attracting notice, were: a slight torus palatinus, crowded teeth, the left lower eye tooth and the four lower incisors being arranged in a straight line forming an angle of ninety degrees on each side with the rest of the teeth; furthermore some coating of the tongue, flat feet, and a rather fine tremor of the hands.

In the further course, the patient, under a régime of outdoor exercise, consisting of tennis playing, lake-bathing and swimming, work with shovel, rake, and tennis roller, in a few days became cheerful, went at the sports and the work with full zest and enthusiasm, greatly enjoying them. His sleep and appetite improved markedly, and self-confidence returned to a great extent. Patient also noticed subjectively an improvement of memory, shown objectively in a reading test, he giving a good report of the page of a novel, read aloud to him and then shown him to glance through, although he stated that before his illness he could have given a more accurate reproduction of what he read.

He also on July 24, ten days after admission, acquitted himself very nicely, and with good speed, of the task of typewriting some notes to dictation. He stated with satisfaction that he would not have been equal to the task a week or a month previously. He rarely had to have a phrase repeated to him while performing the task.

August 7, 1915: Patient had a slight relapse last week, lasting about three days, when he felt less confident, less hopeful of getting well again, sleeping less well. The relapse coincided with the end of the period of prolonged heat and humidity. Since then he has been sleeping increasingly better, usually until daybreak, with hardly any but occasional interruptions of a minute or so.

Bowels have kept regular, at least once daily, right along. Appetite somewhat less good during the relapse mentioned, but very good since.

Sept. 3, 1915: Steady improvement since date of last note. Had three successive nights when he slept without a break from 10 P.M. until 6 and even 7 A.M. averaging from 7 to 8 hours per night. Self-confidence has increased. Thinks now most times that he will be equal to the requirements of the position he last occupied. Appetite very good. Bowels regular, at least once daily. Splendid physical appearance.

Very good response to memory and attention test, made a few days ago. Was given to read the society news of a local paper and reproduced with fully normal accuracy, if not better, the details of the contents read, rendering these at the same time in a manner showing very good attention and digestion of the material read.

Has still periods of mild depression when he feels somewhat diffident of his future, but these periods are fugitive.

Patient was discharged on September, 15, 1915, one month after his admission to "The Oak."

On February 4, 1916, in a letter received from him patient wrote: "You must pardon me for not writing ere this, but ever since I am back to the office (Oct. 3) I have been so terribly busy that I have had no chance to do anything. I am very glad to say that not only am I entirely well again, but I can accomplish much more now than I did two years ago and I can see now that already at that time I must not have been entirely well, as the work in the office tired me out so much. I am back to my old position in the office, I am not afraid any more that I will not be able to fill it; on the contrary, I must say now that I am better able to do it than any other one in the office. As said before, I am entirely well and happy that I can work without being tired."

Depression of the Lyric Composer, Franz Schubert.—The following autographic description of a depression comes from the pen of the famous lyric composer, Franz Schubert, and is rendered here because it so aptly portrays the mental state of a patient suffering from such a depression.

"In a word, I feel the unhappiest, most miserable man in the world. Imagine to yourself a man whose health can never be put to rights again, and who from despair over it makes the thing worse instead of better all the time. Imagine to yourself a man, I say, whose most brilliant hopes have come to naught, to whom the happiness of love and friendship offers nothing but, at the most, pain; to whom enthusiasm (at least of the stimulating kind) for the beautiful threatens to vanish, and ask yourself whether that is not a miserable man, an unhappy man? 'My peace is gone, my heart is heavy, I find them never and nevermore.'* This I may well say every day, for every night when I go to sleep I hope never to wake up again and every morning announces anew to me the grief of yesterday. Thus joyless and friendless do I spend my days, if sometimes Schwind did not visit me and direct at me a ray of those past sweet days."

Another depression, illustrative chiefly of the mental insufficiency, the dearth of ideas accompanying it, is autographically described by the great German poet Goethe. This description is given below in this paper under the heading "Vocations fitted to the manic-depressive temperament." Under the same heading will be found a third autographic note of a depression of the Russian author, Gogol, as quoted by Bagenoff.

Special Types.—It has been brought out by some authors, and of late particularly by Dr. M. Gregory, that the cases of dipsomania are nothing else but special types of manic-depressive insanity. Many points certainly speak in favor of this conception. For these patients usually do not show the "spree," *i.e.* periods of alcoholic debauch, as an isolated symptom. On the contrary, they usually or very often show general mental changes in connection with it, changes which have decidedly a hypomaniacal character. As an illustration I quote from Dr. S. E. Jelliffe's paper on cyclothymia,[2] in which he refers to dipsomanic types of cyclothymia and quotes the periodic mental changes to which the well-known writer, Alfred de Musset, was subject and which were associated with alcoholic debauches. His own brother, Paul de Musset, describes these as follows:

"At times at the bottom of an armoire he had an old yellow boxcoat, with six mufflers, and which could be wrapped about him three times. Thus muffled up, he would lie down on the floor of his room and hum in a lamentable tone some old contemporaneous air. Then in the evening he would cast aside these rags and put on his best clothes. This change of decoration was sufficient to change the course of his ideas. He would leave to make a tour of the cafés of Paris, where the pleasures of the world made him forget the reverse of fate. Soon he would be in a fever of excitement. He worked without interruption until the morning. When he appeared at breakfast I did not notice any signs of fatigue on his face. He had as his fantasie the month of May. The muse possessed him. During the day he would take the lead in conversation and work like a chess player who plays two games at one time. At times he would leave us, to write a dozen verses, and then return to chat with us. But at night he returned to work as he would to a lover's rendezvous. He had late supper served to him in his room. He purposely asked for two services, in order that the muse should have her place designated. All of the lights were lit. He lit twelve candles. People of the house, seeing this illumination, would think he was giving a ball. On the morning of the second day, the piece having been accomplished, the muse took herself away; but she had been so well received that she promised to return. The poet blew out his candles, went to bed, and slept until evening. On awakening, he reread the verses and could find nothing to retouch."

*Quoted from Marguerite's words in Goethe's "Faust": "Meine Ruh ist hin, mein Herz ist schwer, ich finde sie nimmer und nimmermehr."

After the inspiration—daughter, it may be, of excitation—here is the other stage: "Then from the ideal world in which he had lived for two days the man fell brusquely to earth, sighing as if one had awakened him from a delirious and fairy-like dream. After the enthusiasm there followed all at once an ennui, a distaste for ordinary life and for its petty miseries, a deep melancholy. In order to relieve himself from such a depression, it seemed that all the luxury of Sardanapolus, all that Paris could offer of distractions and of refinements, could hardly suffice."

George Sand, in describing similar periods observed by her on Alfred de Musset, made the "sorrowful disclosure of his dipsomania." She said that he accused her of smothering his genius in wishing to destroy his fever. When she believed him to have come to the limit of disgust in his excesses, he appeared to be anxious for more. When she told him to return to the world, he feared her jealousy and threw himself into gross and mysterious debaucheries. He would come home drunk, with his clothes torn and his face bleeding.

Undoubtedly many manic cases of *drug addiction* too are built up on a manic-depressive basis. Their impulsive make-up leads them to correct their nervous states or symptoms by means of stimulants or sedatives or hypnotics, as the case may be. In the manic state there is usually craving for stimulants like alcohol, tea, coffee, tobacco, to keep up the over-activity which their manic state leads them to. Again the insomnia, increased by such practice, leads to the regular employment of hypnotics, such as sulfonal, trional, veronal, to counteract the state of excitement, and the patients often are unable to give up the habit after the maniacal state has passed; and if, as in the cyclic cases, an attack of depression comes on in the meantime, a new source for insomnia is created and the hypnotic is kept up. Thus on a periodic basis a permanent drug habit may be grafted.

Dr. Eva Charlotte Reid[3] in a very interesting paper points out how the addiction to drugs observed in some prominent English authors was really to a great extent the result of periodic pathological states of the manic-depressive type and presented, like these pathological states, a corresponding periodicity. Thus, in speaking of de Quincy's "Confessions of an Opium Eater," which confessions, as most readers probably know, referred to de Quincy himself, she mentions the fact that these were written in a few weeks (while in a hypomanic state), but that "when the proofs were returned, his period of hypomania having passed, he spent six months in trying to correct one volume. She also states that Coleridge was interrupted in writing "Kubla Khan," an opium dream, and never could complete the poem.

Fugitive or Fleeting Types.—Here should also be mentioned the interesting types which Gregory[4] quotes from literature and describes from his own vast experience: "mild and short attacks of a manic-depressive psychosis which may closely resemble the normal variations in mood." These, he says, "have been described by writers on psychiatry." He emphasizes, however, that while for the most part these reports have been of attacks of more than a week's duration, he not only has observed attacks of manic-depressive psychosis ranging in duration from a few hours to several days, but even finds them very frequent, an important point brought out by him.

He points out that they are often mistaken for transitory mental conditions of other character, such as hysteria, psychic epilepsy, migraine, neurasthenia; furthermore, that they may be associated by the patient with disturbances of bodily functions and interpreted as common physical ailments, whereas the general practitioner, in such case, frequently regards them as nervous dyspepsia, nervous heart, liver, and intestinal trouble.

The Manic-Depressive Temperament or Constitution.—In the beginning of this paper, when giving the classification of the manic-depressive psychoses, reference has already been made to the manic-depressive make-up, temperament, or constitution, which we almost invariably find in the patients subject to manic-depressive psychoses and which may also exist as a latent state, *i.e.* without manic-depressive psychoses developing on its basis. A. Hoch[5] deserves the credit of having called attention to this make-up. The latter quite particularly affects the emotional field; it is quite justifiable, therefore, to speak of a manic-depressive temperament.

The characteristics of this temperament are that those thus affected respond intensely to emotional factors both in feeling and in external expression thereof. They are easily moved to joy and grief, laughter and tears, in response to the emotional stimuli affecting them. They are also apt to have a high and hasty temper, getting easily indignant or angry and as quickly regaining their placid mood. They have usually strong likes and dislikes. Their affections when engaged are usually very strong; they make intense lovers, very fond parents or children. Their mood is subject to rapid and abrupt changes under the influence of the impressions received. The "Himmelhoch jauchzend—zum Tode betrübt," although meant by the poet to apply to a lover, very aptly characterizes this temperament.

The fluctuations of weight which we find so markedly developed in the cyclic cases may also be put down as a frequent manifestation of the manic-depressive temperament.

A further characteristic of this temperament is the manner of reacting to damaging influences like continued emotional strain, protracted fatigue, continued lack of sleep, physical diseases, in a special way, *i.e.* by the appearance of symptoms of the manic-depressive order. If, as a result of physical disease, say, typhoid fever, erysipelas, pneumonia, heart disease, a high fever, etc., a psychosis develops, it will usually show a manic-depressive "coloring," even if the main psychosis should have some special character conforming with the physical disease which gives rise to it.

Adolf Meyer's Reaction Types.—To Adolf Meyer[6] great credit is due for having called attention to these "Reaction Types," of which the manic-depressive is a representative instance. It should be mentioned here that some patients of this group have chiefly a manic, other mainly a depressive reaction type, others a mixed one, manic or depressive reactions occurring according to the nature of the damaging influence giving rise to them.

We may add to this the tendency of resorting to stimulants, sedatives, and hypnotics to find relief for emotional strains, fatiguing influences, unhappiness, insomnia, etc.

Vocations Fitted to the Manic-Depressive Temperament.—A study of the mental characteristics of great musical composers, undertaken by the writer, indicated that a great majority of these possessed what in the last chapter has been described as a manic-depressive temperament or constitution. This fact justifies the reversed conclusion that this temperament or constitution, in combination with other factors giving him mental superiority along definite lines, particularly fits an individual for the musical profession and especially for that of composing. This does not imply that this constitution or temperament is adapted only to the performance of the art of music. It undoubtedly is adapted also to the art of acting as expressed in comedy, drama, tragedy, musical comedy, and "screen acting." In all these fields the play of emotions successfully rendered forms an important part of the activity of those following out the said vocations, and a great emotivity, a great response to those stimuli which act on our emotions, has been pointed out in the previous chapter as a prominent characteristic of the manic-depressive temperament. What is known of some of our great actors, more particularly perhaps the prima donnas and tragedians, shows indeed that in their life off the stage they show marked manic-depressive traits. The irascibility, emotivity, great lack of self-control and of adaptation to the restrictions of social rules and customs, leading to unusual outbursts of passion, to murder and suicide, to divorces, are noted with particular frequency among theatrical folks. The mobility of physiognomy, so characteristic particularly of the versatile actor, is another manic-depressive trait, going a long way in making him successful. This has special reference to the "screen actor" in whom the great mobility of facial expression and of action in general forms an important feature of success.

But aside from the field of music and acting, the manic-depressive temperament has a fruitful field in literature, and especially in poetry. In the paper already referred to, Dr. Eva Charlotte Reid' collected some very interesting material in that respect, demonstrating the manic-depressive traits and in some cases well pronounced psychoses of the manic-depressive type in some of the prominent English poets and writers, such as de Quincy, Poe, Coleridge, Keats, and others. For detailed evidence on which this conclusion is based, the reader is referred to the original paper.

Goethe.—That the great poet Goethe was a cyclothymic, results from studies of Moebius,[7] made partly on autobiographical material furnished by Goethe himself, going to show that he had periods of depression indicated by inactivity and insufficiency, alternating with periods of exaltation. One of these depressions is described in his own words as follows: "The winter passes and I do nothing. I cannot accomplish anything. My spirit is incapable of any effort. I submit to this state with patience. I have passed so many times through similar periods. I have learned to suffer and to be resigned. I cannot work, I cannot read, I even cannot think, except in short lucid moments." And again in a letter dated November 3 of the same year: "What state! What suffering! The morning and the evening do not exist for me any more, no activity, not a clear idea."

These periods of depression which Goethe himself considered as pathological were followed by periods of exaltation, which, says Bagenoff, were rightly considered by Moebius as hypomanias, and elsewhere Goethe himself speaks of "a cycle of good and bad days which revolve in my soul. The faculties of invention, of execution, of method as well as of humor, joy, sadness, energy, weakness, initiative, prostration—all moves in a regular cycle."

Gogol.—States of exaltation and depression following each other in cyclic order were likewise observed in the famous Russian author Gogol, who, according to Bagenoff, thus described one of his own hypomaniacal states: "I really do not know whence comes to me this afflux of freshness of energy and of braveness, which I have never felt as yet. I feel the ideas buzzing in my head like a swarm of bees; my imagination has become extremely subtle." But this state was of short duration, to be followed brusquely by a nervous irritability, increasing out of all measure and joined by an indescribable anguish. "Rome and the sky of Italy have lost their charm for me. I don't see them any more. I don't feel them any more. Oh, how painful it is to reveal my state. . . . but you must know. Tear up my letter." (Letter to Pagodin.) Alfred de Musset's dipsomanic form of cyclothemia has already been mentioned.

Bagenoff makes indeed a contention which he is about to produce evidence for, in a monograph in course of preparation, that in cyclothymic persons of talent and genius the hypomaniacal state opens up the subconscious and puts into action a powerful factor of creative imagination and of artistic, literary, and even scientific production.

Thus the writer's contention that the manic-depressive constitution fits its possessors particularly to the vocations of musician, actor of stage and screen, poet and author, finds a strong support in the view promulgated by Bagenoff on the basis of great experience and elaborate study.

Prophylaxis and Treatment of the Manic-Depressive Temperament and Psychoses.—In undertaking the treatment of a manic-depressive, it is essential to explain to him or her the nature of his or her mental make-up and some of its physical characteristics. He must be told that the tendencies to ups and downs, the susceptibility to disturbances of sleep, of appetite, of intestinal function, and the liability to great fluctuations of weight, under the influence of the emotional, fatiguing, and other factors acting on the central nervous system, denote an instability of the nervous system and that the treatment must, therefore, be one of stabilization, both mental and physical, in view of the interaction between mind and body.

In effecting this stabilization, correction has to be made along the following lines:

(1) *Physical Stabilization:* An important point is the regulation of the processes of nutrition and assimilation. According to whether he is elated or depressed, the manic-depressive is apt to overeat or to underfeed himself. The greater the underfeeding occurring in depressed phases, the more is overfeeding apt to follow, with a corresponding overweight resulting.

The intake of food* should therefore be stabilized by making the taken quantity more or less even. In cases of cyclic insanity it will prove most efficient to begin this regulation during the normal phase, carrying it as far as possible through the depressed and elated phases.

The quality of food is another point to be considered. Anything interfering with the easy performance of digestive function and with a normal general metabolism is to be avoided. Meats should thus be restricted, not only in quantity as compared to other food, thus changing the *general quality* of the food-intake, from a proportional point of view, but also in quality. White meats, such a chicken, lamb, fish, should be favored if not exclusively used. The freshness of meat and other decayable food is an important item, as the ingestion of old meat may give rise to acute diarrhea, followed often by constipation. These intestinal "upheavals" as tending to counteract the "stabilization process" should be carefully avoided.

Fried food, as a frequent source of fatty-acid intoxication, from the rancid disintegration of fat taking place in frying, should as much as possible be cut out. The intake of fat is an important point of regulation. In this respect one should remember the fat percentage of certain foods. Eggs, for instance, according to König, contain, the white 0.25 per cent., the yolk 31.70 per cent. of fat. Certain fish are very rich in fat contents, salmon 13.53 per cent., eel 28.40 per cent., red carp 8.73 per cent.; others, particularly the "flaky fish," are poor in it. Of meats, goose and pork are particularly fat, squab especially lean.

Butter should be fresh and its quantity regulated by the general needs of the organism and by the quantity of fat taken in other ways. On the whole, there is a tendency to overuse of fat in cooking, which should be avoided.

Excess of acids is to be avoided, to prevent hyperacidity with subsequent gastric disturbances and acidosis; and particularly the stronger acids, like vinegar, should be used in very spare quantity. Lemon may be advantageously substituted for vinegar in salads.

A certain amount of fruit, particularly fresh fruit, is to be favored, especially to regulate the movement of the bowels, but it should be only mildly acid. This should be considered in the selection of the apples, oranges, grape fruit, peaches, strawberries, etc., bought in the market. The degree of ripeness plays a considerable rôle in this respect.

Green vegetables, such as spinach, lettuce, asparagus, green peas, and beans, should be given freely, not so much for their nutritional qualities, although spinach is valuable for its marked percentage of iron, phosphorus, and lime (Lorand, l. c.), and green peas and beans are high in protein and carbohydrate value, as for their "ballast" making qualities, thus favoring intestinal peristalsis. Recently I have seen very favorable anti-constipational results by the regular administration of salted peanuts, the Spanish variety, one ounce every morning and evening. It is essential, however, that they should be fresh, free from rancidity, and preferably well roasted.

Milk, fresh and fermented; eggs, cheese, particularly the fresh kinds, like cream cheese and pot cheese, should form important items of food for the manic-depressive, being rich in protein, lecithin, and fats and easily digested.

Lorand points out that the digestibility of milk is increased by the addition of bread. Milk should not be given in large quantities, however, although in the heat of summer it can be given much more freely than in other seasons.

Since, particularly in the depressed states, we often find the patients presenting anemic conditions, manifested by a pale, pasty color of the face, an increased oxygenation, as gained by a predominant out-door life in the open country, is an essential feature, increasing the resistance of the patients to fatigue and other debilitating influences. Indoor occupations are injurious to such patients.

Hygiene of Movement.—A certain amount of muscular exercise is very helpful in maintaining that physique which enables the patient to offer a greater resistance to the damaging and thus unstabilizing influences of fatigue, lack of sleep, continued emotional factors, etc. Owing to the increased power of his muscles the patient has the satisfaction of not finding every muscular effort a source of exhaustion. He acquires the pleasure of muscular action, in compliance with Spencer's law that function, if normal in its nature, gives pleasure. However, the selection of the kind and measure of muscular activity is a factor the value of which must not be underestimated. In the first place, it ought to be as much as possible of an outdoor kind so as to add the advantage of increased oxygenation by good air and light to the metabolism improving effect of muscular action. Another essential point is that the muscular activity be general, with such alternation of the muscles put in action as to give them rest and action successively, thus avoiding overaction and overfatigue of one group or another. This avoidance of overfatigue is to be a general guiding feature, not only in muscular, but also in mental work, as overfatigue leads to discouragement, increasing the depression and interfering with sleep. Proper alternation of activity and rest is, therefore, very important.

Another weighty factor in this selection of the muscular activity is the element of pleasure connected with it. An activity, therefore, which gives pleasure by itself is naturally to be given preference. In this no doubt individual taste and training play an important part and what would give pleasure to one may prove a bore to another. On the whole, however, I have found one activity which rarely fails to give pleasure, to young people at any rate. I have in mind the sport of tennis, and this sport combines so many of the other qualities which I have pointed out as being valuable in improving the physique of the manic-depressive and

*For much inspiration in regard to the dietetic treatment of manic-depressives the writer is indebted to his friend Dr. Joseph Fraenkel, as he is also for some other points in their therapy, although Dr. F. may not fully subscribe to the general plan outlined here, nor to many of its details. The suggestions received were partly from private conversation, partly gained in consultation. The writer likewise owes valuable hints to the book of Lorand, "Health and Longevity Through Rational Diet," published by the F. A. Davis Company, Philadelphia, 1916.

thus stabilizing by the increased resistance gained thereby against damaging factors, that I consider it the sport *par excellence* for the manic-depressive, particularly in the depressed stage. The outdoor element, the healthy alternation of muscular groups in action, the pleasure of successful return of balls, the complete mental relaxation which full interest in the game leads to—and it rarely does fail to arouse this interest—all these factors have a healthy effect, especially on the depressed patient who sees that he still is capable of enjoying something and of accomplishing something, even though it be of no direct use. The indirect use he soon begins to feel instinctively.

The quickness of action and of thinking, the latter being eminently automatic and no source of mental fatigue, are valuable aids in the confidence and cheer-restoring process and soon the patient notices also that the thinking in other occupations, such as the digestion and retention of what has been read, becomes easier and coupled with a renewed interest.

The patient should always be impressed, however, to keep the health factor of the sport paramount and not to be misguided by a too sport-like spirit into an overindulgence, such as might ensue in the endeavor to finish a game (*i.e.* set), no matter how long the same may extend itself, or in the chivalrous intent to give the opponent the chance of reprisal, etc.

Sea and lake bathing, especially for swimmers, gives additional muscular exercise of a pleasureable and healthful kind. Gardening and similar work also contribute to give the pleasure of muscular action, together with the advantages of the outdoor life.

With regard to elderly persons, especially women, it is often difficult to induce them to take any other muscular occupation than the domestic work around kitchen and rooms that they were used to as housewives. It is interesting to observe then how the same work which at home was a burden and a source of discouragement to them, becomes a pleasure and satisfaction when done for "health" in company with others. The difference is that at home it was a duty which had to be fulfilled no matter how weary they were; and the displeasure and lack of interest thus developing, soon made the work increasingly difficult. The same work when done outside of the home, for health's sake, and dropped whenever it fatigued a little, not done as a duty, but as a pleasure, and alternating with rest and amusements of a quiet kind, soon lost its harmful qualities, becoming, on the contrary, a curative agent.

Regularity of Life, of Sleeping, Eating, and Stool Habits.—Along wtih the measures of physical stabilization mentioned so far must go others concerning the habits of living. Regularity in the hours of retiring at night, rising in the morning, partaking of meals is very important.

Constipation is one of the most prominent symptoms to deal with, particularly in the depressive patient, and therefore requires special attention. The depressed state itself retards intestinal peristalsis and the semivoluntary act of defecation. But the constipation often is found to have existed years before and in many cases certainly is greatly contributed to by neglect of establishing a regular habit of defecation, and equally essential as it is to counteract constipation by a proper diet already pointed out, is it to establish a regular stool habit, *i.e.* to attend to the act of moving the bowels at the same hour every day. This not only creates a periodicity for the involuntary intestinal motor function, thereby greatly stimulating it for the definite act of defecation, but it also establishes that often subconscious automatic memory which guarantees the daily performance of the act with the certainty of the daily winding of the watch, of which indeed we so often appear entirely unconscious.

Mental Stabilization.—This must follow aims similar to those of the physical stabilization. The patients must learn to get a hold on themselves. They must not allow themselves to become the plaything of their emotions, to give in to every impulse. Just as it is important to lessen the great fluctuation in weight in a rational manner, so is it vital to avoid the extremes along mental lines and to favor the medium states. "Who laughs too much will cry," is a popular saying with a sound basis, following the law of action and reaction. These patients are too prone to let themselves go in grief as well as in joy and must be taught to counteract this tendency. As in emotions, they are also apt to "overdo" in other things, letting themselves go to extremes in amusements, with lateness of hours and encroachment on sleep, as they do in work, physical as well as mental. This they must try to overcome, as much as circumstances and their make-up allow.* They must avoid both physical and mental overfatigue, partly by so arranging their work wherever it lies in their power to do so, that there is a frequent change of the kind of work, thus allowing a resting of cerebral parts and muscles engaged in one activity, while keeping others in function.

It has already been mentioned that the element of pleasure plays an important part in the healthfulness of an activity, mental or physical, or both. It is therefore quite essential that the vocation or profession selected be a congenial one, adapted as much as possible to the peculiar temperament.

While a morbid introspection, an anxious nervous watching for symptoms is to be decidedly condemned, a healthy self-observation, noting and heeding of warnings of nature, such as beginning insomnia, loss of appetite, nervousness and haste, difficulty in concentrating, etc., should be fostered. The patient may thus perceive in time that he has passed normal limits in one field or other and may take corresponding precautions. A tendency to stifle these warnings by resorting to stimulants, sedatives, or hypnotics with a view of thus rectifying matters is again to be combated. The manic-depressive, as has already been stated above, is only too prone to resort to these means, including alcohol, tea, coffee and tobacco, to set himself to rights again and may thus easily become a drug addict.

Treatment of Hypomanias.—This can be dealt

*This control over themselves is not to be repression. It would be unjudicious to counteract to a great extent their propensity of "opening up" to their friends, of "unloading" themselves of emotional burdens. One should aim, however, to keep them within proper limits in these directions.

with briefly, as the main points have already been discussed. In addition to the measures enumerated, some additional features should be observed here, however. With the tendency to overaction, physical as well as mental, regular periods of complete repose once or twice a day, varying from one-half to one or one and one-half hours, on a resting lounge or even in bed, are often very beneficial.

Restriction in the intensity, extent, and duration of amusement and of muscular feats is particularly here in order. The regularity of life and of habits discussed above also applies here, as does the restriction in the use of tea, coffee, tobacco and alcoholic stimulants to which there is a particular tendency in this state.

Erotic trends should have close surveillance, particularly in young girls. However, as said before, great discretion should be used in that respect and severity avoided, so as not to frustrate the good efforts by the antagonism created. This refers also to the combating of the masturbatory habit so frequently found in this case and as often disappearing by itself when the hypomania subsides. In cases of the cyclic kind more stringent measures, acting as safeguards relative to the erotism, may have to be resorted to; for example sterilization, particularly in girls, may prove to be very desirable. This, to be sure, will not cure the psychosis, but may relieve unfortunate mothers of the constant anxiety that the patient "may go wrong" and by becoming pregnant bring disgrace on the family.

Treatment of Depressions.—It has been pointed out already that during a depression a manic-depressive usually shows marked physical signs, an anemic, pasty appearance, a coated tongue, loss of appetite, constipation, insomnia. These manifestations therefore require special therapeutic attention. To stimulate the appetite and digestion, including intestinal peristalsis, secretogen in doses of one tablet t. i. d., taken at meals, often does good service. To this it is good to add a general tonic counteracting the anemia, such as the phosphoglycerates of lime and soda or syrup of hypophosphites, two teaspoonfuls t. i. d.; or one-grain doses of thyroid extract t. i. d. may be used to stimulate a sluggish metabolism. The diet at first should consist chiefly of milk, eggs, vegetables, and fruit, adding to it later gradually the white meats, chicken, fish, and lamb, in moderate quantity.

In addition to the diet and the other anticonstipation measures described under the heading "Physical Stabilization," it may be necessary to use special means for counteracting the constipation, usually such a prominent symptom in the depressed state. A lubrication of the intestine and its contents by means of Russian oil, one tablespoon every morning and evening, is often very helpful as a starter, but the aim should be to reduce gradually the dose and rely on the anticonstipation diet and other measures alluded to. An occasional physic, preferably a saline, like magnesium or sodium sulphate, or a combination of the two, one-half a tablespoonful of each, may be necessary, but a regular daily physicking or a daily enema is to be decidedly advised against.

An outdoor life greatly helps to combat the anemic condition. Short walks are usually helpful from the very beginning, gradually to be made longer, as the improvement progresses. The seeing of pretty scenery helps much in the beneficial effect. Muscular exercises of the kind recommended under the heading of "Hygiene of Movement" should soon be added or installed from the very beginning.

The mental therapy must be chiefly one of encouragement and of stimulating interest and good cheer. It is vital to assure the patients that they are suffering from an actual disease, but one they will recover from and to explain to them the interaction between mental and physical signs. Every improvement noted must be pointed out to them. They themselves are very reluctant to acknowledge any improvement, showing great lack of confidence in the gains made. As to amusements considerable discretion is to be used. If they are of the too boisterous kind they are apt to make the patients worse rather than better. They feel keenly that they cannot enjoy themselves as others do, which creates an unfavorable reaction. Motor rides, listening to well-selected music, which can now be so easily furnished by a phonograph, games like croquet or tennis, etc., usually have a favorable effect. When the patient has advanced somewhat in improvement, moving picture shows, if properly selected, may help to cheer up and arouse the interest, which it is so important to stimulate.

In sanatorium treatment it is usually indicated in the beginning to forbid visits of relatives or friends until the patient has become used to the new surroundings, losing the distress of being separated from his family and friends, and reaping the benefit of the breaking away from the painful associations of home life.

Too long or too complete severance of communications with family and friends must as a rule be avoided, however, as it is apt to give food and substance to delusions that something has gone wrong at home, that the children are sick, the people at home have lost interest in the patient or want him or her to stay in the institution, or the like.

A PROPHYLACTIC VACCINE AGAINST THE SO-CALLED SPANISH INFLUENZA.

By WARREN B. STONE,

SCHENECTADY, N. Y.

COUNTY BACTERIOLOGIST; DIRECTOR OF THE PATHOLOGICAL LABORATORY OF THE ELLIS HOSPITAL; PRESIDENT OF THE NEW YORK STATE ASSOCIATION OF PUBLIC HEALTH LABORATORIES.

THE primary object in the preparation of this vaccine was, if possible, to protect the nurses of the Ellis Hospital from the complication of bronchopneumonia, which practically is the only cause of death in this disease. Soon after beginning its use, however, its prophylactic power against the influenza itself became so apparent that its use was extended very generally to the citizens of the county.

As it was believed that a vaccine requiring more than one injection was impracticable for use in an epidemic so overwhelming as was this, it was planned to prepare a vaccine containing all of the organisms found in the sputum of early cases of influenzal bronchopneumonia, test the protective power of one injection and subsequently make a careful study of the individual organisms, provided the vaccine demonstrated any immunizing power.

It may here be stated that the vaccine did not contain the Pfeiffer bacillus.

The first recorded case of this malady appeared in the city on the fifteenth day of September and, within a short time enough cases were in the wards of the Ellis Hospital to afford considerable material for study. For many days the sputum in every case complicated with bronchopneumonia was typed and, almost invariably, the pneumococcus fell into Type IV. Three of Type III were found in one hundred and twenty-eight specimens, but no Types I or II.

A vaccine was prepared and, on September 30, twenty-four of the hospital nursing staff were injected. Thirty-two nurses failed to receive the injection.

At the end of two weeks, not one of the vaccinated nurses had contracted the disease, although eight of the unvaccinated ones became ill and four developed serious bronchopneumonic complications. The vaccinated nurses cared for the cases complicated with pneumonia, were overworked, and although they wore masks, were constantly in an atmosphere of contagion. The nurses who were not injected were not so thoroughly exposed to infection.

As soon as it was learned that a vaccine was in preparation, physicians wished to aid the experiment, and within a few days thirty-five out of seventy-nine had submitted to the injection.

One of the vaccinated doctors developed a very light attack, while eight of the forty-four unvaccinated became ill and three developed bronchopneumonia.

On October 5 the demand for the vaccine became so large that it was made in quantities and supplied to almost every physician of the community. Altogether 12,362 persons were vaccinated; 3,300 at a station established at the hospital and the remainder by physicians at their offices, in the homes of patients, and in the larger manufacturing plants.

The test was rigorous. It started before the epidemic had reached its height and continued until it had completely subsided. Those injected were invariably told of the experimental nature of the procedure, none refused the treatment because of this, and it may be said that the physicians of this community are convinced that the vaccine possesses a distinct protective value. It may also be said that the reputation of the medical men of this community has not suffered because of its use.

Of the 12,362 persons who were vaccinated but 117 developed influenza, and over one-half of these became ill within twenty-four hours after vaccination, demonstrating the fact that injection had been given in the incubation period. Four of these cases were complicated with bronchopneumonia and there was one death.

Many interesting incidents are related by physicians, pointing toward the protective value of the vaccine; many tell of one member of a family refusing the treatment, and later that one was the only member to develop the disease.

One physician was called to a family where five children were ill with bronchopneumonia; a sixth child had escaped infection. The mother stated that this child was at the home of a neighbor when the members of that family were being vaccinated, and he had received the treatment with the rest.

Of course, such occurrences may be termed just coincidences, but when seventy physicians tell of them they should be given some weight. Foremen in the large manufacturing plants have pointed out an interesting phase of the experiment. When the epidemic was at its height, and many of the shops were almost depleted of workmen and those remaining were becoming demoralized, the men were taken in groups to be vaccinated. There was a complete change of morale for the better. The men became cheerful, and many who had remained at home because of fear of contagion were vaccinated and returned to work.

Several letters could be quoted from presidents of companies employing numbers of men. The vaccine had been used in these factories with an influenza incidence of less than one per cent. of those vaccinated, while it was from fifteen to twenty per cent. among those who objected to the injection.

The vaccine was prepared as follows: Collect six specimens of sputum from cases of influenzal bronchopneumonia, not older than forty-eight hours (the sputum should be as free as possible from contaminating sputum and saliva). Each specimen is washed in several changes of sterile 0.9 per cent. saline, placed in a sterile mortar and ground for five minutes. The culture medium is human blood agar (2 c.c.-10 c.c.), the blood being taken from individuals who had not had influenza nor had been vaccinated. The ground sputum is spread thinly over one or two of the blood agar petri dishes, with a long, flexible sterile cotton swab, and incubated for a period of twenty-four hours.

Then a few cubic centimeters of sterile saline are poured into one of the dishes and the growth is washed off into the salt solution. As soon as an even suspension is procured, the swab is used to seed from ten to twenty blood-agar plates and they are incubated for twenty-four hours. The growth is washed from these, saving one or two plates for future seeding purposes.

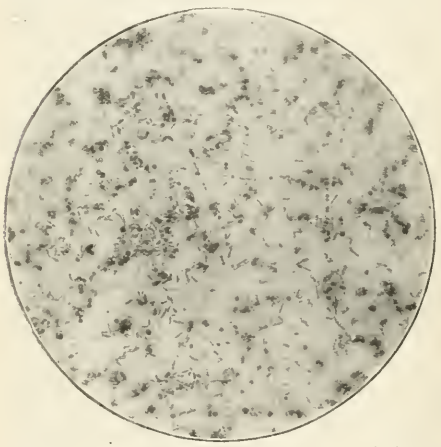
The suspension is poured into a sterile measuring flask, the washings from twelve plates being usu-

ally made up to four hundred cubic centimeters. It is filtered through very thin cotton and five cubic centimeters are placed in a Hopkins' tube and given 2800 revolutions per minute for one-half hour. It is standardized at three per cent., sterilized at 56° C. for seventy-five minutes, and 1½ per cent. of phenol is added. Before using, tests for sterility are made. The dose is 25/100 c.c., which is given subcutaneously, preferably with a tuberculin syringe.

The reaction is usually very slight, and it is believed that the immunity established lasts for a period longer than four weeks. In order to keep up the virulence of the organisms and to ward against overgrowths and contaminations, we made fresh cultures from the sputum every three or four days.

Every plate was examined as to its bacterial content, and it was remarkable to observe the uniformity, both in regard to the kind of organisms seen and the amount of growth.

The only bacteria found in 100 per cent. of the



A carbol fuchsin (1:8) stained smear of an original blood agar plate showing the pneumococcus and gram negative bacillus. 1 × 1000

plates were the Type IV pneumococcus and a rather large gram negative bacillus.

The *Streptococcus hemolyticus* was frequently found in the early almost uniformly fatal cases, but later completely disappeared from our cultures. Occasionally the Type III pneumococcus, the *Staphylococcus aureus* and *Micrococcus catarrhalis* were grown.

In about eight per cent. of the plates we found the Pfeiffer bacillus, but as it was absent from the first vaccines made, which were apparently efficacious in producing immunity, we discarded for vaccine production all cultures containing this bacillus.

By averaging many plates, it was computed that the dose of vaccine contained approximately 500 million each of the pneumococcus, Type IV, and the gram negative bacillus, also 25 millions of other organisms, including the *Streptococcus hemolyticus*, the *Staphylococcus aureus*, and the *Micrococcus catarrhalis*.

It was believed that the pneumococci in the vaccine would prevent the pneumonic complications, but it did not seem probable that the pneumococcus was the cause of the influenza. Suspicion naturally turned to the gram negative organism, which was found in every plate and was also isolated from the pus of two cases of empyema, complicating influenzal pneumonia. It is from 1 to 3 microns in length and about one-half in width. It is motile and does not ferment the sugars. It is non-pathogenic to the mouse and guinea-pig. It does not give one the impression that it is a disease producer; however, complement fixation, agglutination, and precipitin tests are being carried out in hope that something definite may be found.

In conclusion we would like to state that we believe this vaccine has proved its value in preventing the so-called Spanish influenza and the broncopneumonic complications. Our experience leads us to believe that the Pfeiffer bacillus has no etiological relationship to this disease.

ELLIS HOSPITAL.

PRINCIPLES UNDERLYING THE SURGICAL TREATMENT OF CERTAIN INFECTIONS ABOUT THE SACROCOCCYGEAL REGION.

BY ARTHUR A. LANDSMAN, M.D.,

NEW YORK.

ASSOCIATE SURGEON, DISEASES OF THE RECTUM, POST GRADUATE MEDICAL SCHOOL AND HOSPITAL, ATTENDING RECTAL SURGEON PHILANTHROPIN HOSPITAL, DEPUTY SURGEON, DISEASES OF THE RECTUM, NEW YORK HOSPITAL, OUT PATIENT DEPARTMENT.

IT would seem at first thought, that nothing could be gained by a discussion of the treatment of localized infection, because surgical science already has definite and well-established ideas on that subject, but every one familiar with certain pathological conditions commonly found about the sacrococcygeal region will admit that the results of their treatment are far from satisfactory by reason of recurrences which are only too frequent, even at the hands of men of skill and experience. In point of fact, there is such a striking disparity in the results of those infections, when compared with such as occur in other parts of the body, as to compel the conviction that they belong distinctly in a class by themselves. We estimate from our personal knowledge based upon hospital and private work, that fully 20 per cent. of all patients suffering from the diseases which are under consideration here, are obliged to submit to operation repeatedly before they are rid of their trouble. As we know there is no effect except as the reflection of an adequate cause, the question must arise in every inquiring mind what this cause (or causes) may be, and how it may be prevented or overcome.

Let us look over briefly the pathological conditions which may occur in this region:

1. Simple acute suppurative inflammation, characterized by (a) superficial lesions, such as furuncles, retention cysts, etc.; (b) deep seated lesions, such as abscess, periostitis, or osteomyelitis of neighboring bony structures.

2. Syphilis in the form of condylomata, ulcerations, gummata, chancre, spread by extension from the anal region.

3. Tuberculosis of (a) the soft parts, either primary or secondary, a part of peri anal, anal or rectal tuberculosis; (b) the bone, involving the lumbar, sacral or coccygeal vertebra.

4. Infections from congenital tumors, cysts or teratomata; sacrococcygeal meningocele, spina bifida.

5. Chronic infections from the burrowing of fistulous tracts posteriorly.

6. Ulcerations from malignant growths, epithelioma, adenocarcinoma, sarcoma; fibroids, lipomata, etc.

7. Ulceration from gonorrhea, chancroids, etc., occurring in women secondary to genital or rectal infection.

8. Miscellaneous actinomycosis (?) anthrax(?)

It would be manifestly impossible within the limits of this paper to take up for discussion every one of the conditions enumerated above, besides being wholly unnecessary, because the treatment of most of these is along lines which are well understood, and its limitations generaly recognized; it will require but a moment's thought to determine that our problem is in group 4, and that congenital tumors or cysts are the surgical affections with which we are concerned here.

Sacrococcygeal tumors or cysts are congenital lesions, which may be either endodermal in origin, when they result from the embryological remains of the postanal gut, or ectodermal, when they arise from enclosures of adjacent epithelial tissue, such as the neural canal, or any portion of the central nervous system, and may be classified broadly as tumors of the postanal gut (rectal), and postrectal dermoids. Tumors of the postanal gut grow from that portion of the caudal extremity of the enteron which is below the point where early in fetal life the proctodeum joins the neurenteric canal to form the lower end of the intestinal tube; when two have joined, the part below the point of union, having no physiological function to perform, shrinks up, atrophies, and finally comes to be represented by a vestigial fibrous cord. If however, by reason of traumatism—and this appears to be the clinical history of many cases—infection or any other exciting cause it becomes activated into pathological growth, it develops into a structure which contains vesicles resembling intestinal glands, in accordance with a well-known biological law, that when an organism has attained its full development, its cells invariably reproduce the kind of tissue from which they themselves arise; on the other hand, postrectal dermoids originate from inclusions of adjacent epithelial tissue, which in course of growth has accidentally become separated, cut off, and enclosed in other tissue. Being ectodermal in origin, they necessarily reproduce elements which are derived from the epithelium, hence we find in them hair, skin, teeth, mammæ, rudimentary brain substance, etc.

As these tumors differ biologically and structurally, it is but natural to expect clinical differences among them; these are not without surgical significance, and may be summarized as follows:

A. *Tumors and Cysts Derived from the Ectoderm.*—1. Those of epithelial origin are far more common. Out of 682 consecutive rectal cases observed in the Rectal Clinic of the Post Graduate Hospital, on the surgical service of Doctor John F. Erdmann, there were 8 cases of sacrococcygeal tumor; all of these belonged to the type of post rectal dermoids, as their clinical character showed.

2. They contain for the most part strands of hair rolled into a ball, or arranged in the form of sheaves; other epithelial derivatives, while described, are very uncommon.

3. They are located dorsal to the sacrum and coccyx, below the level of the lower third of the sacrum, and unless complicated with true fistula, their tracts ramify upwards, rather than toward the anal margin.

4. They seldom attain large size, generally not exceeding that of a pea or bean; sometimes they are so small that they have to be carefully looked for, and the wound diligently searched before they are discovered.

5. They are apt to be multiple, and occur in pockets or nests; this explains recurrences even after thorough dissection.

6. They are more common in men, and between the ages of 18 and 50. The youngest patient we had was a boy of 15, while the oldest was a man of 84, seen on the service of the Home of the Daughters of Jacob.

B. *Tumors Derived from the Endoderm.*—1. They are rare.

2. They are seen soon after birth, at any rate in early infancy.

3. They are generally single.

4. They grow from the remains of the tube into the post rectal space, or anteriorly, pushing the structures of the pelvis forward. They are never located dorsal to the sacrum.

5. They are usually larger in size.

6. They are made up of vesicles, resembling intestinal glands.

We shall take up for consideration in this paper sacrococcygeal tumors of epithelial origin, because they form a majority of such lesions as seen by the general practitioner, and belong to the class which typifies the difficulties in treatment which have been mentioned.

The usual history obtained from a patient suffering from an infected sacrococcygeal cyst or tumor is, that for a variable period—often following trauma of the lower spine—he had experienced burning pain in the region on assuming the sitting posture, felt the parts to be swollen, and noticed a thin, dirty grey, gruel-like discharge. Occasionally there may be some fever, with general aches and pains especially in the lower extremities, but there are no intestinal disturbances, no bleeding from the rectum, no discharge of pus or mucus from it. A local examination discloses one or more brawny, indurated, discolored areas near the median line, below the lower third of the sacrum, and occasionally an opening from which a drop of purulent material may be squeezed out, often containing some hairs. The most natural thing to do, is to incise it, evacuate its contents, and drain the cavity, which is followed by temporary relief, but by no means disposes of the trouble permanently; sooner or later there is a repetition of the cycle, and our records show that a good proportion of these patients have to submit to operation again before they are cured. The reason is clear; we can

not expect permanent relief if we are content to remove what are obviously only the effects of the lesion, without disturbing the cause responsible for them; plainly the suppuration is only the result of something which for the time being acts as a foreign body and a focus of bacterial infection.

In the light of the above, it follows then, that the proper thing to do in every case of localized suppuration of the sacrococcygeal region is: (*a*) To determine the nature of the trouble; (*b*) to remove its cause, if possible, by suitable surgical means; (*c*) to attend to the necessary after treatment.

In order to determine the true nature of the trouble, it is advisable to look over the pathological conditions as they are found to occur in this region, and exclude them one by one, by such means as must readily suggest themselves to every one of us. It might be helpful to repeat categorically the following:

1. Sacrococcygeal tumors or cysts are the most common lesions found in this location.
2. They occur below the lower third of the sacrum, dorsal to the bone.
3. They are chronic in their course.
4. They exude a thin, greyish-white purulent fluid, rarely thick, creamy, or ill-smelling.
5. They frequently contain hair and detritus in a gruel-like material, seldom any other epithelial elements.
6. They are often in the medial line, at any rate in the vicinity of the anal dimple.
7. Occasionally there are two or more indurated areas, because of the multiplicity of the lesion.

To permit thorough removal of the cause, it must be emphasized, that the first prerequisite is general anesthesia; while local anesthetics have justly earned a definite place in the surgery of the anorectal region, they are not suitable for work which requires extensive dissection. It is necessary to open the wound wide, follow the tracts and curette them, make a careful search for all pockets and nests, remove foreign bodies, old scar tissue, and such portions of the wound edges as appear to be badly infected, and look after the postoperative treatment in the usual way. It may not be amiss, however, in this connection, to mention some points which are not unimportant: that the underlying bone must be searched for evidence of disease, because some cases either begin as an inflammation of the bone, or the process is later communicated to it from the soft parts; that when the burrowing leads downward toward the anal canal there may be perforation into the walls of the rectum, which requires division of the sphincters for the establishment of proper drainage; that the more chronic cases may be caused by specific infection, as in one reported by the writer before the New York Physicians' Association, which was due to tuberculous degeneration. In any event, it is advisable in every case to submit a specimen of the tissue for laboratory examination, in order to learn the true nature of the pathological process, and be prepared to deal with it.

310 West Eighty-sixth Street.

Mortality of Lima.—The death rate of the Peruvian metropolis has decreased in 50 years from 49 to 27 per 1000.—*Cronica Medico-Quirurgica.*

REFERENCES TO HAIR BY RABELAIS.

By Douglass W. Montgomery, M.D.,
San Francisco.

An Abundance of Hair as Indicating Great Strength and Bravery.—It will be recalled that Pantagruel, like his father, Gargantua, before him, had a rather notable birth. Gargantua was born through his mother's ear, and Pantagruel, although he came into the world in the natural way, was so large that his mother died of the effort. When he was born he was all hairy like a bear—tout velu comme un ours—whereupon one of the midwives cried out that he would do marvelous things, and if he should live he would reach a great age.[1] The same idea that hairiness, bravery, and strength are associated is expressed in the name, le poilu, the hairy one, given admiringly to the modern French infantryman.

Manner of Cutting and Dressing the Hair.—The human animal, having no fixed way, like his fellow creatures, of wearing the hair, has delighted in treating it in all sorts of fashions, combing it, curling it, clipping it short or allowing it to grow long, twisting it, braiding it, tonsuring it, or wearing a wig over it. In the Middle Ages the manner of wearing the hair was of great importance, as it frequently denoted the social status of the individual. It constitutes a telling point, for instance, in the description of Maistre Janotus de Bragmardo, who was commissioned by the Sorbonne to recover the bells which Pantagruel had stolen from the towers of Notre Dame de Paris.[2] He is said to be "tondu a la cesarine"; that is to say, to have his hair cut after the fashion of the Cæsars, the short warrior cut of the Romans. It is needless asking why these very efficient military leaders went clean shaven and had their hair close cropped. The helmet fitted better, and besides it was a mattter of hygiene, as it did away with two chief nesting places for certain vermin very prevalent during active campaigning.

Others have thought that Rabelais' reference was to the great Julius himself, who was bald, and who became so quite young. It would appear that he was sensitive in regard to this defect, as he wore a floral wreath to hide it, when electioneering in Rome. It would be quite edifying to see some war horse of the Democratic Party—democracy was the particular brand of politics professed by Cæsar—so decked out when on the stump in California.

Still another explanation for the short hair of the above-mentioned Bragmardo is that Francis I, King of France, had received a wound in the head, which required him to have his hair cut short. Because of this the courtiers and everyone else wore their hair in a similar way, just as the modern German cocks up the ends of his moustache ridiculously in imitation of the Kaiser.

The tonsured head of the monks gave rise to many a joke. For instance, Friar John, while on a military expedition, rode under a tree, and the stump of a branch caught in his helmet. While so hooked his horse rode from under him and left him suspended in the air. Instead of helping him his companions began to crack jokes upon his predicament, and among other things compared him to Absolem, the son of David, who was similarly sus-

pended from the branch of a tree by his hair. Attention was drawn to the difference as well as the similarity by saying that as the monk was tonsured and had no hair he was hung by the ears. Friar John expressed freely his opinion of the merry companions who could find time to make game of him while in such a position. Finally they let him down, and he showed his contempt for defensive armor by taking it all off and scattering it about the field, and then clad only in his monastic habit and armed with his staff he went gaily forward with the others to battle.[3]

Friar John was tonsured, but monks of other orders, as for example the Quavering Friars, fashioned their hair differently. In order to show that they despised the world and its goods they shaved the hinder part of the head and neck down to the shoulder blades, so that from behind they looked like pigs. The hair in front, from the bregmatic bones (parietal bones) forward, was allowed to grow as it would.[4]

In another chapter Rabelais tells how by a certain ceremonial consisting of drawing a shirt over their robe, clipping their hair, and muttering certain apotrophic or harm-averting and expiatory words, men were changed into birds.[5] By birds he meant monks, and birds some of them appear to have been.

A Seborrheic Type.—Maitre Aedituus, sacristan of the Ringing Island, was an old duffer, small of stature, bald, with a richly illuminated nose and crimson face. Pantagruel and his companions, after having fasted, bore him a letter of introduction. After a fast was a most opportune time to meet with a man showing the attributes enumerated above. Maitre Aedituus, knowing that these worthy gentlemen had fasted, made them very welcome, and saw to it that they were plenished, and afterward made them acquainted with the noteworthy singularities of the Island,[6] which they undoubtedly saw double.

A small, chunky man, a generous feeder, and the possessor of the kind of nose and face as above described, is almost always bald, and his smooth dome glistens with oily seborrhea. Besides alopecia, oily seborrhea, and rosacea, such men are liable to a long list of other skin diseases of a seborrheic type, such as seborrheic eczema and senile patches, as well as certain infections of a staphylococcic and streptococcic nature, causing acne, furuncle, and infective eczema.

The Personification of Lent.—Rabelais describes his personification of Lent as being a demigiant with downy hair and a double tonsure.[7] When hair falls because of seborrhea it gradually becomes finer and frailer, and finally ceases to appear altogether, and the person becomes completely bald in that situation. Other explanations have been given for this passage, but this seems to me to be the natural one, and is a creditable piece of medical observation on the part of Rabelais.

The Hat as a Cause of Disease.—The hat has frequently been accused of causing disease, and Grandgouzier, so careful in every particular in choosing the dress of his son, the infant Prince Gargantua, especially mentions caps fashioned like the crust of pastry, as being likely some day to cause a mischief to their closely cropped wearers.[8] It is not the cap cocked on the side of the head that we nowadays blame for causing baldness. It is the stiff and formal stovepipe hat, which is supposed by some to act by pressing on the temples, and interfering with the arterial supply. Baldness goes merrily on, however, no matter what kind of hat is worn.

Combing the Hair.—In two interesting passages Rabelais refers to Gargantua's way of managing his hair. First he gives a long list of his infantile ineptitudes when he was between three and five years of age. He says that like all the other little children of the country he passed his time in drinking, eating, and sleeping, in eating, sleeping, and drinking, and in sleeping, drinking, and eating. These were his chief occupations but there were others of a more temporary nature such as wallowing in the mire, slobbering his nose, dirtying his face, treading his shoes down at the heel, and gaping at flies. Occasionally he would vary the above by wiping his nose on his sleeve, snivelling in his soup, and rubbing his belly with a basket. But what particularly interests us in the present situation is that he combed his hair with a bowl.[9]

Farther along, in his very detailed description of the studies and the way in which Gargantua passed his time as a student, Rabelais says that, after getting up he put on a coarse frieze gown lined with fox skins, and then combed his hair according to precepts laid down by Almain, a learned professor of that period, which was accomplished by using his four fingers and his thumb, for his preceptors had taught him that to comb his hair in any other way or to wash and clean up was to lose time in this world.[10]

His father, seeing that this kind of education did not bring the results desired in a young prince, turned him over to the care of Ponocrates, a young, alert tutor, and Eudemon, an equally accomplished youthful companion. Even the names of these two were significant of their qualities. Ponocrates meant work and force (πόνος work, and κράτος force), and Eudemon a good angel (εὖ well, and δαίμων a spirit). Under these guides, Gargantua throve marvelously both in his capacity for merry-making and for absorbing useful knowledge.

After such an infancy and such an education, Gargantua grew to manhood and led his troops to battle. In a notable encounter at Vedewood he suffered a severe cannonading, and afterwards, in combing his hair, more than seven cannon balls tumbled out at every rake of the comb. These had been shot at him by the enemy and had remained in his hair ever since the fight. His father thought they were "cooties," and questioned his son minutely in regard to them.[11]

The Alleged Phenomenon of Hair Rising From Fear.—That hair stands up on the head from fear is an old and widespread belief. This belief evidently arises from the feeling of cold shivers and the sensation that the hair moves when under the influence of the strong emotion of fear. It is, of course, impossible for the weak erector pili muscles actually to cause the hair on the human scalp to stand up so as to be observed as erect. Rabelais says that at the mere sound of certain fear-inspiring names he has seen the hair of a nobleman stand on end.[12] This, of course, might be written

by Rabelais as it might be written by many an author of the present day, just for its literary effect and without any idea of the actuality of the occurrence, but it may readily be that the occipito-frontalis, one of the most powerful cutaneous muscles we possess, moves under this strong emotion, and so may give rise to the sensation in question.

Sayings and Proverbs Relating to the Hair.—There are several of these sayings in Rabelais' writings and one of the wittiest of them was uttered by Ponocrates, one of the companions of Gargantua, in urging prompt action in pursuing an enemy. He reminded his associates to take Time by the forelock as Opportunity had no back hair.[13] It appears that this is taken from a distich of Canton, Fronte capillata, post est occasio calva.[14] Gens a tout le poil is untranslatable.[15] It means folks who stick at nothing.

Panurge had been in many a tight place, but never in a more desperate situation than when he questioned Trouillogon, the ephectic and Pyrrohonian philosopher, on the difficult question as to whether he should or should not marry. The ephectic philosophers were so called because they suspended judgment in all cases. After putting the question in many forms Panurge in desperation cried out: "Now let us turn it quite the other way, against the hair."[16] If the questions previously had been put with the hair, or directly, those put a contre poil, against the hair, succeeded no better, and poor Panurge had to fly next to taking counsel of a fool.

I believe I have personally met some ephectic philosophers and they are particularly tantalizing when the office is full of patients, and one is trying to get a direct answer out of them to help in solving a knotty question in diagnosis.

When a person has "a head" on him from taking too much alcohol, an old remedy is to take some more alcohol, to take a hair of the dog that bit you. This remedy Friar John suggested to Panurge, when that worthy took to rhyming and spouting doggerel,[17] and Friar John affected to believe he was drunk.

The Middle Ages was a great period of symbolism, and the most characteristic of the above references to the hair are symbolic as the one referring to the hair as indicating strength, and the ones describing the peculiar fashioning of the hair by the monks as tonsuring, and otherwise shaving in a peculiar manner. In the Middle Ages almost every gesture seems to have had its special signification and in medicine symbolism was carried to a ridiculous extent. For instance, the yellow color of rhubarb was a symbol of the liver, and was considered the real reason why this drug was curative in hepatic disorders.

IS THERE A CLINICAL ENTITY IN ACUTE VASOMOTOR PARALYSIS?*

(PRELIMINARY COMMUNICATION).

BY FREDERIC J. FARNELL, M.D.,

PROVIDENCE, R. I.

PASSELER, Romberg, and their coworkers of the Leipzig Clinic were among the first to observe the importance of the blood vessels per se in acute infections and concluded that cardiac failure was not one due to an infection but one due to a vasomotor paralysis. They also attributed this paralysis to the action of the poison or agents upon the nerve conters.

If one now considers the symptom-complex manifested in the peripheral circulation, one observes a low or fall in blood pressure and an altered distribution of the blood causing edema, etc. How often, when these symptoms become manifest, does the clinician immediately turn his attention towards the heart and kidneys and various symptomatic diagnoses are made—myocarditis, nephritis, cardionephritis.

The object of this short report is to offer a few facts, (1) clinically, (2) pharmacotherapeutically, and (3) pathologically in favor of acute vasomotor paralysis.

CASE.—"Harry;" age 45; married; a professional man of standing; heavy smoker; temperate habits. He appeared for examination August 9, 1916. Chief complaint "cardiospasm," accompanying physical disorders, periodic attacks of asthma, pain around the heart, dyspnea upon going upstairs, hyperacidity. All these symptoms became exaggerated under emotion and undue stress of business.

Clinical Examination: Blood and urine negative in every respect. Eyegrounds normal. Functional tests of kidney and stomach normal. No evidence of focal infection in throat, tonsils, nose or ears. *X*-ray of the heart showed apex 8.8 cm. to the left of the median line; right border 4.4 cm. to the right of median line; total transverse diameter 13.2 cm.; length of heart 14.2 cm.; diameter of base 10.4 cm. Possibly a slight enlargement of right side of heart. Electrocardiographic findings: Normal rhythm. Very large "P" deflection indicative of auricular hypertrophy as with mitral stenosis. *X*-ray of gastrointestinal tract: A distinct play at the cardia but no definite obstruction or irritability. Stomach normal, good sphincter and cap. Remainder of tract normal. Deductions: Autonomic irritability with a possibly enlarged right heart. Pulse 84. Blood pressure 118.

Dividing the autonomic system into its various parts according to the pharmacological action of drugs, three units are formed: (1) The synapse in the autonomic ganglion, (2) the end apparatus in the viscera or tissue, and (3) the cell in the spinal fluid of the central apparatus. Poisons acting upon the synapse first irritate and then paralyze; example, nicotine and tobacco poisoning. Those poisons acting upon the end appara-

*Presented before Boston Neurological and Psychiatrical Society, February 21, 1918.

tus in viscera or tissue do so in two ways, (a) autonomic irritability produced by the pilocarpine group and autonomic inhibition by the atropine group; (b) sympathetic irritants due to adrenalin and sympathetic inhibition due to no known agent. Those poisons acting upon the central apparatus are (a1) autonomic central excitants-picrotoxin; (a2) autonomic inhibition-botulismus toxin; (b1) sympathetic excitants-cocaine, atropine, and caffeine; (b2) sympathetic depressant-morphine, chloral hydrate, etc. In none of these systems is there a sharp line of demarcation by means of a distinct selective action of the drug, which is due to the fact that the drug acts on other centers and to the inherent neurogenic tendency towards mutual antagonism between the divisions of the systems. This overlapping is quite confusing and disappointing to the clinician who is seeking immediate results.

In the case in question the provocative type of pilocarpine was given with merely the usual pharmacological effect, no exaggeration. This was obtained only after two weeks' administration of the fluid extract. At that time it was discontinued and atropine sulphate, gr. 1/150 a day, prescribed. All symptoms of autonomic irritability were relieved for two and half months. In January, 1917, he developed an acute influenzal infection of the upper air passages with several severe attacks of true asthma. He developed ulcerations about the nose and mouth which were later secondarily infected. The patient ran no elevation of temperature. Atropine had no effect. Adrenalin, 1/10,000 by mouth, caused a subsidence of the disorder in two days and the patient remained quite well until April, 1917. On April 4 he developed an attack of rapid breathing which interrupted his sleep. These attacks became more severe during the next four days so that on April 8 when seen by the examiner he presented paroxysms of apparently difficult breathing and yet there was no change in color of the mucous membrane or facies and no distinct anxiety. The chest revealed prolonged inspiratory and expiratory rhythms with a few sonorous râles. There was no irregularity in the heart rhythm. Pulse ranged between 80 and 90, and blood pressure was 120 even during his attacks. Atropine aggravated the condition. In the beginning adrenalin had no effect but later controlled his paroxysms greatly when used hypodermically. Psychic treatment and mental diversion controlled him wonderfully well. On April 12 the patient developed edema of the ankles, scrotum and penis became enlarged. There was a partial subsidence of the edema upon lying down. A trace of albumin was observed in the urine at this time but no casts. 150 c.c. of 5 per cent. sodium bicarbonate solution intravenously caused complete disappearance of the albumin. During the last two weeks in April this breathing difficulty became so marked that it was necessary to resort to morphine in addition to the adrenalin. These two drugs could keep him comfortable for a period of three or four hours. Finally cardiac distress and respiratory discomfort became severe and led to the development of edema of the lungs which resulted in the patient's death May 6, thirty-three days after the onset of his respiratory difficulty.

It is the writer's feeling that this respiratory difficulty and the disorder in peripheral circulation was distinctly one of a vasomotor type and probably secondary to some poison or agent affecting the central cell. So that, in reviewing the entire picture, one observes that the three units so formed as divisions of the autonomic system had undoubtedly been affected at some time or other during the progress of this disease process and that the ultimate result was a complete central vasomotor paralysis.

The microscopical examination of the heart and kidneys showed the following heart section—there is a probable thinning of the heart muscle fibers and some widening of the space between the bundles which is probably an artefact. There is no indication whatever of myocarditis or endocarditis. Kidney sections along the tubules in the vertex of the pyramids are seen small hemorrhages and some oozing of red blood cells into the surrounding tissue. This is not a pathological disorder. The general appearance of the kidney was normal, no increase in tissues to indicate interstitial nephritis and no pathological disorder in the functioning portion of the kidney, tubules, glomeruli, etc., to indicate a "Bright's."

In view of the distinct negative pathological findings in the heart and the kidneys, the approximately negative or normal findings in electrocardiographic tracings of the heart and normal functional tests of the kidney, it would seem only proper to infer that the pathological disorder bore a relation to the vascular system which is under autonomic control. The question of split protein products, bacterial poisoning, and the reduction of protein by body enzymes has not been considered in the summary description of the disorder but should undoubtedly be kept in mind.*

In conclusion it might be stated that whereas text books on theory and medicine merely refer to acute vasomotor paralysis, it would appear from the facts presented that there may be a disorder in the connecting link between the heart and kidney, namely, the blood vessels, and only the future will tell of the importance of a more thorough study of the autonomic system and its relation to the peripheral circulation.

59 Blackstone Boulevard.

THE "ENDLESS CHAIN" TREATMENT OF PNEUMONIA.

By CHAS. R. HUMBERT, M.D.,

KANSAS CITY, MO.

PATHOLOGIST TO THE KANSAS CITY GENERAL HOSPITAL, COLORED SECTION.

THE prevalence of influenza and pneumonia with their high death rate makes it imperative to resort to heroic methods of treatment rather than to follow the accepted ones only. The lack of serum or other specific remedy for influenza together with the inability to obtain antipneumococcus serum forced me to use convalescent serum. The economical phase together with the clinical value obtained in even such a small number of cases seemed to justify a thorough trial of it.

The Endless Chain.—It is a well-known fact that persons convalescing from pneumonia have antibodies in their blood stream. As soon as the patients' condition permits therefore, they are bled as much and as frequently as possible. The bottles used for collecting the blood are rinsed in normal saline and autoclaved. After the blood is collected it is allowed to stand at room temperature until the serum separates. It is then pipetted off and centrifuged. The clear serum obtained is now heated to 56°c. for thirty minutes.

*Sudden death in the present epidemic of influenza has resembled in some respects an overwhelming toxemia affecting the vasomotor system.

Tricresol three-tenths per cent. is used as a preservative. This treated serum is placed in stock.

When another patient comes in with pneumonia the type of pneumococcus is determined immediately and treatment is begun. When convalescence sets in, the above procedure is repeated. It is a case of one gives serum to two, two gives serum to three, and so on, the procedure becoming endless.

Compatibility Test.—It is very important that recipient's corpuscles be tested against the donor's serum. Several serums are tested in order to be sure of getting one from the group that will not cause agglutination.

Syphilis and Tuberculosis.—No attention is paid to syphilis in donors. Granting that living spirochetes are present in the blood stream they would be killed by the heating process—fifty-six degrees centigrade for thirty minutes. Tuberculosis should be eliminated by frequent sputum examinations after the crisis, making a differential cell count as well as the blood examination.

Treatment.—The serum is administered intravenously. It should be given only once daily unless the condition of the patient is critical. As high a dose as 170 cc. has been administered without any untoward effects. Reactions occurred in only two cases in each being of a mild character.

Results—The number of cases treated is eleven: Type I, 2; type II, 4; type III, 4; type IV, 1. There was one death—type III. All others had an uneventful recovery except one. This patient has a venereal infection. This small number of cases is reported in order to interest physicians and determine the efficiency or lack of efficiency of convalescencent serum when used type for type.

Medicolegal Notes.

Complaint Failing to Allege Negligence of Physician Is Insufficient.—In an action by an employee against his employer and its insurance company for damages for injuries alleged to have been caused by the negligence of a physician, also a defendant, employed by the two companies to treat the plaintiff for an injury received, the court sustained demurrers to the complaint for the following reasons: The liability of an employer and its surety at common law and under the California Employers' Liability Act for the negligence of a physician employed to treat an injured employee is secondary to and dependent upon proof of the physician's negligence; and it was held that the complaint failed to state a case of negligence or malpractice on the part of the attending physician. The complaint alleged that the physician undertook to treat the plaintiff, "but did not use due, proper, reasonable, or any care or skill in treating plaintiff's injury, but, on the contrary, carelessly and negligently treated said injury in this." Then followed several paragraphs in which the course of treatment pursued by the doctor was set forth. It was alleged that for a time the plaintiff's leg remained unset, except in splints, and that on a certain day the splints were removed, the leg set, and a cast put on; that thereafter the cast was taken off, and, it being found that the leg had not knitted, it was rebroken and reset and a plate and longer cast put on, which last cast was taken off after 9 days and a shorter cast put on, and that thereafter the plaintiff was discharged by the physician, returned home, and remained in bed for four weeks. On or about July 4, 1913, and more than 90 days after the accident, it was discovered that the leg bones were not knitting, and the plaintiff called upon the defendants to furnish the treatment necessary to cure him, which demand was refused. Under the provisions of the statute there is no duty imposed upon the employer to furnish treatment to an injured employee for more than 90 days after the injury, and therefore no liability on the part of any of the defendants could be predicated on their refusal to treat the plaintiff after June 18, 1913. The remaining allegations of the complaint set forth the course of treatment pursued by other physicians, the expenses incurred in obtaining such treatment, and a general damage clause.

The court said that in pleading their case in the manner above set forth the plaintiff's counsel evidently misapprehended the law as to the duty and liability of physician to patient. Their brief was wholly directed to the question of the liability of the corporation defendants, and the sole reference to the law of physician and patient to be found in their brief was the following phrase: "As to the liability of Lohse (the physician) it seems a case of res ipsa loquitur." What they really pleaded was a non sequitur, for the description of the course of treatment pursued by Dr. Lohse, contained in the complaint, was entirely consistent with his having exercised all necessary care and skill in treating the plaintiff, and it did not follow from nonsuccess that Dr. Lohse was negligent.

As was said in Houghton vs. Dickson, 29 Cal., App. 321, 155, Pac. 128, the implied contract of a physician in taking a case is that he possesses a reasonable degree of learning and skill in his profession, and that he will apply the same to the treatment of the case; and if he possesses and uses such skill therein he is not liable for the result, for a physician, of necessity, is not a warrantor of cures. "Negligence on the part of a physician consists in his doing something which he should not have done, or omitting to do something which he should have done," (McGraw v. Kerr, 23 Colo. App. 163, 128 Pac. 870), and in order to charge him with liability, some such negligent act or omission must be alleged in the pleading. In the absence of such allegation, it will be presumed that the physician has used the necessary care and skill.—**Foreman v. Hunter Tumber Co.**, (Cal.), 173 Pac. 408.

Public Health Commissioners—Distribution of Milk.—The Maryland Court of Appeals holds that under Baltimore City Charter the mayor and council had authority, in the exercise of the police power therein expressly conferred upon them, to pass Ordinance No. 262 of 1917, regulating the production and distribution of milk and milk products in the interests of cleanliness and health. The ordinance was held not unconstitutional as depriving milk dealers of their property without due process of law. It is not invalid as attempting to confer on the commissioner of health unlimited discretion in granting, refusing, and revoking permits to and of milk dealers; as failing to provide for proper notice and hearing before the commissioner of health as to the issuance or revocation of milk dealers' permits; as failing to provide an appeal from the exercise of discretion of the commissioner of health; or as attempting to delegate power to the commissioner of health in that it attempts to empower him to make regulations for the sale of milk, etc. The fact that milk producers and distributors, owing to war conditions, had not been able, in the five months allowed by the ordinance, to make the changes in dairies and farms required by it, was held no ground for holding unreasonable or enjoining enforcement of an ordinance deemed necessary for the discharge of the city's duty to preserve the public health.—Creaghan v. Mayor, etc., of Baltimore, Maryland Court of Appeals, 104 Atl. 180.

Expert Testimony as to Value of Physician's Services.—The Washington Supreme Court holds that where application is made for a commission to take the depositions of five physicians as to the value of professional services rendered by the plaintiff physician, it is discretionary with the trial court to limit the number to three. Such evidence consists of pure opinion with reference to something that is neither exact nor scientific. Such expert evidence, even if uncontradicted, is not conclusive, but merely advisery—only a guide. Such physicians may testify as to the reasonable value of a physician's services in the case of a disease known of by all physicians, although the services were rendered by a physician in a different city from that in which the testifying physicians are practising.—Terrill v. Fotheringham, Washington Supreme Court, 173 Pac. 748.

Military Medicine.

Cases of Stammering from War Shock Treated by Psychotherapy.—Writing in the *Medical Journal of Australia*, September 28, 1918, Dr. Clarence G. Godfrey states that during the past two years a number of cases have been referred to him for treatment by hypnotic suggestion at No. 5 Australian Garrison Hospital, in which stammering or stuttering has developed, or has been revived, after years of disappearance, as the result of shell shock or of various war stresses. In the majority of these cases there had been in addition to the speech disorder, certain neurasthenic conditions, such as persistent muscular tremors, insomnia, functional paralysis, and so on, which had disappeared or diminished, but the stammer had remained as a severe and distressing defect.

It is pointed out that in all these cases the active cause is the psychic disturbance. Practically all the patients exhibit a temperament showing nervous excitability and many of them have a definite neurotic history.

Realizing the psychic origin Godfrey is treating these cases by applying, in the first place, psychotherapeutic methods, supplementing these, if necessary, with the recognized procedure of the expert who treats stammering and stuttering.

Each case of stammering, therefore, which has come under his care at the base hospital, he has hypnotized, and although he thinks it is premature to speak of results as cures, they have been at least gratifying. The method that he has invariably adopted, has been to induce a hypnotic sleep or lethargy, and to suggest to the patient that he is now perfectly at ease mentally, that he can now pronounce the stumbling words as easy as any other because his vocal mechanism is sound and intact, that where nervousness has interfered with his normal powers, the nervousness is no longer felt by him, that nothing prevents him from being able to speak clearly, and that he will be convinced of his ability to speak normally when he finds himself doing so on awakening. Godfrey then orders him to repeat after him simple words or sentences and leads up to difficult ones, and, in almost every instance these are spoken fluently and in a normal tone. Strongly expressed suggestions are given to the patient's capacity to speak equally well on waking. Sometimes a patient has been told to keep on repeating some well-known nursery rhyme and not to cease at the signal to awake, although, in the middle of the rhyme, but to keep on talking. He will usually manifest his astonishment at finding himself talking without difficulty. Sometimes a patient will converse on waking without realizing that his stammer has disappeared, until his attention is drawn to it with amusing effect. In several cases, however, it is noticed that the stammer after disappearing entirely for some time, will return, but always in a less degree. In one case the patient spoke perfectly in sleep, at the first attempt to hypnotize him, although he had had a very bad stutter for eight months past, being almost inarticulate. He woke in a few minutes apparently cured, and has been free from stuttering ever since. It has been noticed that every case treated, even the worst, has been able to speak far better in the hypnotic state than out of it, all the interesting influences of emotionalism being then removed or diminished. This, in the opinion of Godfrey, surely establishes the condition as a psychosis rather than a neurosis.

Treatment of Chest Wounds.—William Hutchinson, in the *Canadian Medical Association Journal*, November, 1918, concludes as follows: (1) All cases of wounds of the chest should be treated in special wards or special hospitals; (2) careful charts should be kept which record temperature, pulse, and respiration four times a day; (3) early diagnosis of infection is important; (4) every case in which there is more than two fingers' breadth of dullness should be aspirated; (5) cases of open pneumothorax should be closed as early as possible; (6) cases in which there is a large amount of clot in the chest should be opened, blood and clots evacuated, and the chest closed; this should be done as early as possible; (7) cases in which the hemothorax is found to be infected should be opened, washed out and closed; some antiseptic being left in preferably an emulsion of bipp in liquid paraffin; (8) postoperative aspirations must be done in all closed cases, the first forty-eight hours after operation; (9) no attempts should be made at the base hospital in France to remove a foreign body from the lung.

Injections of Saccharose in Tuberculous Soldiers.—Sergeant and two others have made a trial of the saccharose treatment of tuberculosis as recommended by Lo Monaco and have found it of no value (*Journal de médecine et de chirurgie pratiques*, Sept. 25). The patients all had tubercle bacilli in the sputum and thus it was readily possible to learn whether the treatment could control the essence of the disease. The injections were painful. Sugar did not in any case appear in the urine, the amount injected being five cc. daily of a 50 per cent solution in distilled and sterilized water. It is true that there was an initial gain in weight but this was not maintained. The sputum when weighed showed a decrease in some subjects, while others showed no decrease but instead an actual increase. The temperature was not influenced, neither was the auscultatory expression of the disease. Subjectively the results were better. Patients thought they were benefited and the treatment became popular; they felt better and claimed that their night sweats even lessened.

Convergence of the Eyes in Major Cases of Shell Shock.—Descomps, Euzière, and Merle in *La Presse Médicale* for October 3, call attention to the numerous indecisive discussions on the nature of the phenomenon of shell shock. If it is based in any way on minute organic alterations these should betray themselves sooner or later. Among evidences of organicity is the phenomenon of convergence. The authors have seen this in ten subjects. The phenomenon is, in part at least, an elicited one. Rotatory tests bring it out while it also appears during excitation of various types, notably the galvanic circuit. In the rotation test the patient is turned in one or the other direction

and with closed eyes and after the tenth turn is told to pause and open the eyes which are then seen to converge strongly. The pupils may reach the extreme inner angles of the eyes. This convergence may persist for a considerable interval—in one case a minute and a half. Convergence is not always symmetrical and may be unilateral. In general all other ocular motion is unaltered. The tests are best made on a revolving platform so that the patient remains passive throughout. The muscles of the adductor group evidently overact and the author accepts the convergence as the result of minute organic lesions in the cerebrum. One of the subjects had formerly a paralysis of the sixth pair and the rotation test was not necessary to bring out convergence. The lesions could occur in a variety of localities—motor centers, nuclei of various cranial pairs, association centers or paths of connection. Often other symptoms were present which suggested diffuse lesions in the encephalon. The phenomenon of convergence seems to stand in no definite relationship to nystagmus although in the latter we may see isolated convergence movements. Generally speaking the authors see no reason to implicate the labyrinth in any way in this manifestation.

Sudden Death of a Soldier from Adrenal Sclerosis.—In the *Journal de médécine et de chirurgie pratiques* for October 10, Bazin relates the following case. The patient was an artillery man aged 38, an alcoholic, general condition poor but an excellent soldier. He presented himself for fatigue, backache, and diarrhea. Placed in repose his fatigue augmented. Although under observation several days no diagnosis seems to have been made. The symptoms became aggravated without new developments. Then a cadaveric odor appeared which seemed to emanate from the entire surface. The white line of Sergent could not be elicited. The first diagnosis was asthenia attributed to influenza. The latter had not been mentioned before in the history and was presumably masked or mild. After a day of effort he became worse. He had complained off and on of dyspnea and his pulse had been weak and rapid. Death took place suddenly in syncope. The autopsy showed no tuberculosis, no cardiac lesion and general freedom from organic disease save sclerosis of the pancreas and adrenals. The liver and kidneys showed some enlargement but no histological report was made. Even the pancreas is not accused of contributing to death. Professor Sergent himself made the histological study of the adrenals and appears to regard the sclerosis of these organs as the sole cause of the invalidism and sudden death. The nature of the process is not clear beyond the belief that the attack of grippe, mild as it was, was sufficient to determine the acute symptoms. The glands appeared to have suffered no marked functional compromise and were equal to their work under normal conditions. The blood pressure was not taken but there was absence of pigmentation and of the white line while the gastroenteric symptoms were not of high degree.

The experience of the present war teaches us to be on the lookout always for adrenal insufficiency which appears under different clinical and pathological expressions. The adrenals may be attacked in the tuberculous as part of that disease, they may be involved in any acute general infection, or if already attacked may be made worse; they have frequently given out from overwork, both physical and mental, and, as is known, antityphoid inoculation sometimes develops mild cases of functional insufficiency. Our knowledge of symptoms is increasing as muscular atrophy is noted at times as a result or accompaniment of the profound asthenia. The patient in this case suffered in this manner.

Getting American Sick and Wounded Home.—The American Expeditionary Forces will have all sick, wounded, and convalescent American soldiers back in the United States within two months, according to an announcement from Washington. The number of military hospitals abroad has already been considerably reduced by the Medical Corps. The daily hospital census shows that there are now more than 100,000 hospital beds vacant.

Base Hospital at Tent Camps to Remain.—The War Department has ordered the sixteen tent camps constructed as training centers for National Guard Divisions to be abandoned as soon as possible, but the base hospitals in connection with the camps are to be maintained. These hospitals are at the following camps: Camp Greene, Charlotte, N. C.; Wadsworth, Spartanburg, S. C.; Hancock, Augusta, Ga.; McClellan, Anniston, Ala.; Sevier, Greenville, S. C.; Wheeler, Macon, Ga.; MacArthur, Waco, Tex.; Logan, Houston, Tex.; Cody, Deming, N. M.; Fort Sill, Oklahoma; Bowie, Fort Worth, Tex.; Sheridan, Montgomery, Ala.; Shelby, Hattiesburg, Miss.: Beauregard, Alexandria, La.; Kearny, Linda Vista, Cal.; Fremont, Palo Alto, Cal.

Medical Examinations Before Demobilization.—All troops from overseas are to be kept in observation camps for at least two weeks prior to embarkation, and suspects will be detained until all possibility of the development of infectious disease is over. The health of the troops as a whole is said to be excellent at the present time. Before demobilization every man will be subjected to a thorough medical examination, and careful statistical records kept of his condition. Those found with defects will be kept under medical attention until the defect has been removed or found to be incurable. By this means records will be available that will be useful in the settlement of pension claims later on.

American Women's Hospitals to Continue in Service.—It is announced that the three units of the American Women's Hospitals will continue in active service in France for another six months. The unit of which Dr. Caroline Finley is the head will spend the winter in the vicinity of Nancy. The gas unit will remain where it is at the present time, while a third unit will continue its relief work among refugees in the south of France. This latter unit, at the request of the French War Department, has added a 100-bed military hospital to its civilian work.

Permanent Appointments for Temporary Medical Officers.—The Bureau of Medicine and Sur-

gery of the Navy is formulating a bill which will provide that all temporary medical officers of the Navy be offered an opportunity to qualify for an appointment in the permanent establishment with the rank now held.

The Navy's Loss in the War.—The naval casualties during the entire war, excluding the Marine Corps, and exclusive of those who died of disease, numbered 1,233, according to the report of Surgeon General William C. Braisted. Practically all the deaths in the Navy were due to combats with submarines. Admiral Braisted declares the most important task of the medical branch of the Navy still lies ahead in taking care of the sick and wounded and extending some aid to the Army in this work. Already naval hospitals in the United States are filled. Hospital facilities at Norfolk are so taxed that it is probable the Navy Department will commandeer homes to house sick men being sent here. Hospitals in Baltimore, Philadelphia, and New York may be called on to aid.

Italy's War Losses.—According to the Italian Bureau of Public Information, Italy's total war causalties number 2,000,000. Of these 400,000 were killed or died of wounds, and 100,000 died of disease and other causes. In addition 500,000 are listed as permanently disabled, leaving 1,000,000 who were wounded but not permanently disabled, missing, or prisoners.

Austrian Losses.—Austria-Hungary reports 4,000,000 men killed and wounded during the war, of which 800,000 were killed, including 17,000 officers.

Lieutenant Colonels George E. Brewer and Alexander Lambert of New York were promoted to the rank of colonel on November 12.

Rides for Convalescent Soldiers Wanted—The American Red Cross has called upon 1,000 automobile owners in New York City to provide automobiles and chauffeurs for transporting convalescent soldiers and sailors on recreational tours of the city. This service has been centered in a new division known as the Red Cross Recreation Transportation Department, and will be under the direction of the Red Cross Motor Corps. Owners are asked to give their automobiles for three hours' service weekly. A Red Cross nurse or uniformed member, in compliance with United States Government regulations, will accompany each party.

Germans Merciful to the End.—A correspondent of the London *Times* and New York *Sun* with the British army of occupation says in a recent despatch that everywhere in the reoccupied territory one meets the same universal disgust and loathing of the Germans and hears the same tales of looting. "But the topic of all others to which it is impossible to refrain from referring to is the German treatment of prisoners, especially the British. In all the black history of Germany's conduct in this war there is nothing viler than her treatment of the sick prisoners in hospitals up to the time of the armistice . . . The culminating crime was the last when the Germans made no attempt to hand the hospitals over to any authority or representatives of the Allies. They did not even inform the patients or civilians where they were going, they merely went away and left the patients alone." The consequences to the patients, deserted, without food, medicines, or any one to help them in any way, can readily be imagined.

Hospital Ship Arrives.—The United States Hospital ship *Northern Pacific* arrived at the Port of New York on December 1 with 1,100 sailors, marines, and soldiers on board. Of these 500 were seriously wounded. There were 60 wounded officers, among whom were several belonging to the Army Medical Corps who had been gassed while attending the wounded at the front.

Deaths in the Service.—LIEUT. IRA CONDICT, JR., M. C., U. S. Army, of Hoosick, N. Y., honorably discharged from the service on account of physical disability, August 16, 1918, died of pneumonia at his home, on October 27, aged 32 years. He was graduated from the Albany Medical College in 1912, served with the British Expeditionary Forces in Flanders in 1917, and was invalided from there to the Prince of Wales Hospital, London, then to Osborne House on the Isle of Wight, and later to Netley Hospital, from whence he was returned to the United States and placed in United States Army Hospital No. 1, at Williamsbridge, until his discharge.

LIEUT. WILLIAM FREDERIC CRAIG, M. C., U. S. Army, of Philadelphia, was killed in France on September 26 while caring for wounded soldiers northwest of Verdun. He was a graduate of the Medico-Chirurgical College of Philadelphia, in 1897, a specialist in neurology, and for fifteen years professor of biology, anatomy, and French in the Central High School. While in the service he was on duty at Camp Oglethorpe, Ga., Camp Weir, and Camp Meade, Md.

CAPT. THEODORE DOUGLAS MEAD, M. C., U. S. Army, of New York, an assistant surgeon of the 104th Field Artillery of the New York Division, died on October 30 of wounds received while attending the wounded on battlefields near Le Catelet. Captain Mead was a graduate of Cornell University Medical School in 1912, and before entering the service was a member of the Bellevue Hospital Staff.

CAPT. JAMES FREDERICK MUNSON, M. C., U. S. Army, of Sonyea, N. Y., died from influenza, at his station in Plattsburg, N. Y., on October 25, aged 37 years. He was a graduate of the University of Michigan, Ann Arbor, in 1904, for twelve years pathologist at the Craig Colony for Epileptics, Sonyea, and for several years secretary of the National Society for the Study of Epilepsy.

LIEUT. ARTHUR MORGAN EVANS, M. C., U. S. Army, of Chicago, a graduate of the University of Illinois, in 1916, died from cerebrospinal meningitis in Evacuation Hospital No. 21, Camp Custer, Battle Creek, Mich., on October 5, aged 28 years.

LIEUT. FRANCIS MARION BURKHALTER, M. C., U. S. Army, of Bay City, Ga., a graduate of the Atlanta, Ga., School of Medicine, 1909, died from pneumonia, in France, on October 8, aged 31 years.

CAPT. LAWRENCE EDWARD FLANNAGAN, M. C., U. S. Army, died from pneumonia following influenza at his home in Charlotteville, W. Va., on November 6, aged 54 years. He was a graduate of the University of Virginia, Charlotte, in 1884.

MAJOR JOSEPH BIDLEMAN BISSELL, M. C., U. S. Army, died at his home in New York, on December 2, after a few days' illness. (See page 995.)

THE INFLUENZA PANDEMIC.

THERE can be no doubt that the world has been or still is in the grip of a pandemic of influenza and of the associated affections which habitually follow in its train, such as has not been known in our times; nay, perchance not since the Middle Ages. There is, however, nothing in the pandemic for which ample historical parallels cannot be found, and every characteristic at present reported can be traced in the old records. Such outbreaks have been noted in the earliest records to which we have access, and in their more virulent forms they have usually extended with amazing swiftness throughout the world. It has been well said that influenza is the "crux of epidemiology," and although it is the most elusive of morbid processes to investigate, still it is not to the credit of medical science that so little is known relative to its origin. In the matter of origin, although not necessarily of development, all that can be said with some degree of certainty at the present writing is that it would seem to be quite independent of climate, of race, and of seasonal influences and variations of both weather and winds.

Influenza *per se* is not a highly fatal process, and because for the past twenty years it has appeared only in comparatively mild types the medical profession has looked upon it far too complacently. It has, however, frequently been associated in extreme cases with pneumonia, and what makes this year's visitation most serious is that in all countries people are dying of septic pneumonia, which often supervenes unless the most rigorous prophylactic measures are quickly taken. The existence of diphtheroid conditions of the throat has also been noted in England. It will be well to reject once and for all the fanciful theories which unquestionably exist, largely due to the erroneous belief that this pandemic is something new. It certainly did not originate in malnutrition, because France, England, Spain, and Switzerland are not underfed in the strict meaning of the word. Even if they were, the American continent is not underfed, yet influenza has had a paralyzing effect upon activities in the United States and Canada.

Influenza has nothing to do with the admixture of other forms of nutriment with wheat, as has been suggested. Its extension is not particularly due to the rapidity of modern transportation, for it crossed seas and continents with incredible swiftness when railroads and steamships were unknown. There is nothing novel in the outbreaks at sea, for thousands of instances of the kind have been established. It is not the old English "sweating sickness," which never became pandemic, and disclosed a very different symptomatology. It is not a benign type of pneumonic plague, though in an article in the MEDICAL RECORD of October 12, Dr. King showed that there was a striking similarity in the two diseases, and certain curious cases reported some time ago on a ship at Gothenburg would seem to demand further investigation. Most emphatically it bears no relation to trench fever, which is a louse-borne process. There is no evidence which directly connects the pandemic with the war at all. Typhus, smallpox, plague, dysentery, typhoid fever, and scurvy are diseases of warfare, as has been amply demonstrated in Germany and Austria-Hungary almost since the commencement of the Teuton onslaught, but influenza is not among the generally accepted pestilences of war. However, the possibility that there may be some relation between it and the *consequences* of the war cannot be entirely eliminated. We know little of the connection between mind and disease, and for some years the peoples of the world have unquestionably been in an abnormal and overstrained mental state. The germs of disease are with us constantly, and we carry not a few of them in our bodies in an innocuous state until some subtle change of physical and mental condition makes the human soil favorable for their pullulation, perhaps quickened by contact from without. The surroundings of the continental peoples are less healthy, sanitation has certainly been neglected, drainage has become imperfect, houses have fallen into disrepair, with the inevitable resulting dampness which makes dwellings a hotbed of disease. The shifting of the population has resulted in overcrowding in certain areas, and influenza flourishes in crowds. Though in the allied nations food has been sufficient in quantity, changes in diet among them must have had a bad effect. The lack of sugar, the most easily realized form of energy, has certainly had unfortunate results, especially upon women and children. The milk question and the difficulty about fats are equally serious factors, and should be taken into careful consideration, although all such are absent in this country, which has suffered severely from influenza. The rise and decline of great epidemic diseases have perplexed mankind throughout the ages. Hecker believes that great epidemics had "a cosmical origin." Simon held that "the chemistry of our globe is subject to variations, perhaps definitely progressive or cyclical, in which human epidemics are but a part." Yet the conundrum of influenza should not be insoluble, and we hope before this recrudescence of the disease has entirely subsided that the mystery surrounding it will be cleared away.

PITY THE PARETIC!

UNDER the present system of military practice, when a soldier is discharged from the United States Army for physical or mental disability, the question at once arises whether this disability was acquired in "line of duty" or not; if so, he is given an honorable discharge and a pension, if not, a dishonorable discharge and no pension. In other words, he is kicked out. A disability due to syphilis, unless an extragenital chancre can be definitely proved, is considered due to the soldier's own misconduct and hence not in line of duty. The extragenital chancre may have had its origin in kissing a prostitute. No matter, it is in line of duty. That is, it is a duty to kiss a prostitute, but misconduct to have intercourse with her.

When we consider that of the hundreds of thousands of soldiers who have served in the United States Army before, we will say, venereal prophylaxis came into use, doubtless there are very few who have been soldiers any length of time and have not indulged in some extralegal intercourse and hence exposed themselves to lues. (As to the possibility of contracting syphilis from marital intercourse we will say nothing, for fear of being accused of cynicism.) Of this number some contract syphilis, others, more lucky, escape. Of the former, a few—three or four in every hundred—years later develop nervous syphilis. Why they do, and others do not, no syphilologist has yet been able to tell us. Certainly it does not appear that when a patient has contracted syphilis he can prevent the possibility of paresis by any medicine or treatment, mode of living, charm, or incantation. Thus we see the situation—not an exaggerated one or fanciful, but occurring every day—of a soldier being treated for syphilis by military surgeons, its existence a matter of record in the War Department; we see this soldier honorably discharged at the end of his enlistment with *conduct excellent*, accepted for another enlistment, and another and another, promoted to corporal or top sergeant, serving the Government faithfully and conscientiously for ten, fifteen, or twenty years, marrying, having children, and assuming the responsibilities of a family man, and then paresis develops. The diagnosis at once sets in motion the chain: due to syphilis, not in line of duty, due to patient's own misconduct, dishonorable discharge, no pension.

Any one who has followed a paretic through his brief course of fatuous grandeur, convulsive seizures and wasting away, who has seen these men admitted in the early stages to the insane asylums, apparently in the best of health, and seen them within a few months wither away to noisome living skeletons, as if the curse of some malignant Deity lay heavy on them, will not believe that an iota should be added to their punishment. Let us not then take a faithful soldier who, after serving his country many years, becomes afflicted with this awful curse, and kick him out in disgrace, leaving his family paupers. It is well enough to let the moralists mouth platitudes; perhaps he has done wrong and should be punished. But what more fiendish punishment could the mind of man conceive than general paresis? If he has danced, he is paying the piper with his life. Let us not shame his family and send the widow of a soldier of the United States out begging for bread. Pity the paretic!

A RECENT ACCOUNT OF TRENCH FEVER.

CHRISTOPHE, writing in the September number of the *Archives Médicales Belges*, gives a brief and condensed but up to the minute account of this malady. The latter is characterized by periods of intense fever which alternate with five day afebrile intervals (five represents the mean duration). *Quoad* history it is extremely difficult to state when the disease was first definitely recognized, although it certainly did not antedate the present war. It probably was first confounded with malaria because the latter condition was known to occur in all localities where trench fever first developed. A German wrote of "Russian malaria" and another German of a quintan type of malaria. At almost the same time it was regarded as a special type of influenza, socalled "Polish influenza" and also "periodic influenza." Next topical designations appeared, one of which, "Volhynia fever," proved a catchy name. Another title which was maintained was "five day fever." All of these terms apparently preceded "trench fever" which was to gain the greatest vogue. Beginning among German troops on the Polish frontier this affection ended by appearing on all fighting fronts from Belgium to Mesopotamia.

Trench fever is chiefly a fever of special type which comes on suddenly in the midst of health. The one day fever is followed by say five athermic days after which the temperature again shoots up for one day to 40° C. or more, to be succeeded by five more feverless days. The total number of febrile hours in a seizure is not over five or six. The sudden fall of temperature suggests a crisis which exceptionally lasts two hours or more, and may then be termed an atypical crisis or a.lysis of brief duration. But there may exceptionally be a lysis which lasts 24 or 48 hours. Finally there have been seen lytic phenomena prolonged over four or five days. In the latter rare instance there is hardly any fever-free interval. However the athermic periods may be longer than five days—six, seven and eight days have been noted. Also the interval may be unusually brief—three or four days instead of five, so that here again the patient may not be free of his fever. Next to the latter the chief symptom is tibialgia, which is invariably bilateral and aggravated by pressure and percussion. The seat of the lesion responsible for this pain is still unknown. At the outset pain is clearly determined by the rise of temperature, but when established it does not show parallelism with the latter. Even at times a sharp ascent of temperature may not be accompanied by pain. Of numerous symptoms seen in addition none seems to be in any wise constant

or characteristic. The course shows want of type and there may be from one to eight febrile accesses to the case.

Because of its intrinsic brevity this fever seldom can make any inroad on the patient's general condition. Practically he remains well throughout its course. Various alleged disturbances of general health do not appear to be the result of the fever but of antecedent or coincidental conditions. By reason of the wide range of symptoms, efforts have been made to make numerous clinical varieties of trench fever. The author does not uphold these endeavors at all.

In regard to causation one may provisionally accept the louse hypothesis of diffusion of the malady. But so far as the actual pathogenesis is concerned there is neither consensus of views nor any plausible opinion. Blood parasites of the most varied and opposed types have been accused in this connection. In regard to epidemiology one can only insist that it is a louse-borne malady which rages by preference in the spring.

In regard to significance there is no mortality to speak of and there are no demonstrable sequelæ. What then is the significance of the malady? The answer is that this is purely military. Many men are attacked at the same time and disabled for the moment; also we know that there will be more or less future incapacity for a period which may attain seven or eight weeks. After the last febrile paroxysm the patient must be granted absence from duties for several additional weeks to be on the safe side. Of treatment, whether indicated or empirical, there is none—the author recommends collargol only on the testimony of one man, admitting that he has no corroborative evidence.

TREATMENT OF SOFT CHANCRE AND CHANCROIDAL BUBO.

In 1914 it was noted that the chancroid was undergoing a retrogression in incidence. Once ranging in frequency with the chancre proper, the proportion had in some clinics become 2 to 5, and even less. Nor was this movement peculiar to any one country. But with the progress of the present war the chancroid has again come into its own, and has caused a vast amount of military disability. Special research has therefore been necessary for a prompt, efficient, and practicable wholesale remedy, and such has been found in iodine fumes, according to Petges, Gratiot, and Cottu, writing in the September number of the *Journal de Médecine de Bordeaux*. The method goes back to 1911, and the authors, although they have used it but six months, have treated 236 cases of chancroid, of which 80 were complicated by buboes. Several forms of apparatus are in use for carrying out this treatment. In many cases, cure results in 8 or 10 days. There are, however, large or multiple or deeply ulcerated forms which may require from 2 to 4 weeks for a cure. An open inguinal bubo heals within a month. The authors have seen numerous extragenital chancroids, seated, for example, on the chin, lips, fingers, thighs, etc., and these cutaneous lesions respond especially well to this treatment. There appear to be absolutely no drawbacks to the method. It is not intended to be kept up indefinitely, for it probably retards rather than hastens simple scarring, the object being merely the destruction of the Ducrey bacillus. The iodine vapor is most readily generated from iodoform under the influence of warmth. To treat a bubo, the authors use retractors, after opening by wide incision, and allow the vapor to enter the new cavity. The bulb of a thermocautery is used to force the vapor into the infected area under pressure. Every second day is sufficient for exhibition. The surfaces to be treated are carefully cleansed, and after treatment a powdered iodoform dressing is employed.

Another, though allied, method of treatment of chancroidal bubo is that by injection of a 10 per cent. iodoform-vaseline mixture into the substance of chancroidal buboes after puncture with a bistoury to evacuate the pus. This treatment was proposed originally by Otis of New York, and later by Fontan of France. Since 1893 numerous reports have appeared on the subject, but for some reason, perhaps the retrocession of chancroid as a world evil, the method has fallen into disuse. The recrudescence of the malady during the present war has made advisable a trial of forgotten remedies. The authors announce that this will at times cure a chancroidal bubo in 8 or 10 days. All aseptic precautions are strictly observed. No anesthetic is required. Incision is made wherever there is fluid to evacuate, and the tissues are gently squeezed. The length of incision is 1 to 2 mm. A large cotton compress is applied, with a spica bandage over all. The authors would enforce rest, although the pioneers of this treatment evidently meant it for ambulatory cases. The patient should be well after ten to twelve days. Petges has used this management since 1898, and claims 90 per cent. good results. The combined authors have treated 38 patients in the past 10 months, with a total of 46 buboes. Of this total, 34 recovered in from 8 to 12 days. The special indications are buboes in which fluctuation has just become perceptible. The skin is as yet not involved. There appear to be no unfavorable results, such as iodoform poisoning. The statement that the treatment is unnecessarily long or burdensome is not borne out by facts, for comparison shows that the reverse is the case. It is true that the technique is exacting, but the results are obtained more rapidly than by the expectant method.

Changes in the Adrenals After Burns.

The actual causation of death following burns still remains more or less a mystery. The causes usually assigned, as toxemia from genesis of a poison in the burnt skin, perforating ulcer of the duodenum, etc., by no means cover the subject as a whole. The latter factor is almost negligible, while the former is a mere hypothesis which rests

on the interpretation of certain experiments. To throw some light on this mystery Nakata, a student of Professor Askanasy of Geneva (*Correspondenz-Blatt für Schweizer Aerzte*, September 21), has made a series of experiments with the following provisional report: The experiment animals were chiefly male guinea-pigs and rabbits and the autopsies were held at all intervals from a few minutes to 16 days after death. In all cases of early death—within 24 hours—changes were found in the adrenals in both cortex and marrow. These comprised hyperemia and cortical parenchymatous alterations. The latter involved both the protoplasm and nuclei of the cells and extended as far as necrosis. If the animals lived beyond 24 hours the adrenals showed a remarkable augmentation in weight and size, due to alterations in the parenchyma. The cortex in these cases was hyperemic and often hemorrhagic. The lipoid content was notably diminished. The author seeks to explain these changes by the operation of a toxin. The condition of the adrenals in actual clinical cases in human beings agrees with the author's finds. The toxic theory is therefore upheld and its rationale is bound up in the intermediation of changes in the adrenals. The report does not give full details of the mode of causing death. Apparently, moist heat was employed, and doubtless under full analgesia.

Toxicity of Eggs.

From time to time, at least in France, reports of poisoning attributed to ducks' eggs gain credence. Discussing a recent report to this effect, Carles of Bordeaux (*Journal de médecine et de chirurgie pratiques*, September 25) says that it is now 40 years since Guyon announced the discovery in apparently sound eggs of bacteria, yeasts, moulds, and dust particles. Further investigations revealed the occasional presence of minute stones, grains, insects, worms, fragments of plants, and unique objects like the foot of a beetle. Such occasional finds need surprise no one, for conceivably they could enter the egg at the moment of fertilization and while the egg was still in the oviduct. All of the early studies were, so far as known, made on the eggs of the common fowl, but the method of life of the duck exposes it still more to such contamination. It is given to feeding and playing in polluted water, and fertilization naturally occurs in the midst of putrefying organic debris of all kinds. Copulation may actually occur under water, and the filthy liquid of cesspools and the like enter the female genitals. In theory, poisonous organisms could remain inert until the egg incubated, and under such circumstances eggs are not supposed to be eaten. Moreover, cooking should be sufficient to destroy all germ life. The inference is that insufficient application of heat must be responsible for poisoning. The eggs need not be raw, but the cooking may be of such nature that the germ-bearing portion of the egg is not sterilized.

Narcolepsy of Gastric Origin.

Since Gélineau first introduced the term narcolepsy to indicate "sleeping fits" due to an incoercible desire to doze, many different conditions have been described under this name. At present we have typical narcolepsy and various conditions in which a desire to sleep may be present. It seems evident *a priori* that any physiological state which prmotes drowsiness might supply a predisposition to attacks of narcolepsy. Even after a meal of moderate size taken by a normal subject there is a slight tendency to drowsiness which becomes much more pronounced after a heavy meal, or in dyspeptics. When sleep under such conditions is irresistible we have narcolepsy. The patient may fall asleep so abruptly that he may endanger himself or others. It is characteristic, however, of narcolepsy of whatever kind, that the attack is of brief duration. The victim never collapses, for he always has time to assume a posture suitable for sleep. He may even announce that he must doze for a few minutes, after which he will awake refreshed. He may be kept awake, or readily awakened. Hence there should be no likelihood of mistaking narcoleptics for epileptics of any kind. The digestive troubles are of no particular type—cases have been seen of alcoholic gastritis, hyperchlorhydria, atony, etc. In these patients indigestion is only a determining cause, but relief of the stomach mischief seems to lead to complete recovery. Possibly akin to these gastric cases are others in which a subject falls into an imperative sleep after indulgence in alcohol, but who wakes in a few moments completely sober, instead of passing into a stupor.

News of the Week.

Pryor's Naval Hygiene.—In the notice of this important work published in our issue of November 16, page 873, the author's surname was through error omitted in the transcript of the title, the name being given as James Chambers; it should have been James Chambers Pryor.

New Drug Commissioner.—Governor Whitman has appointed Frank Richardson, of Cambridge, N. Y., as Commissioner of Narcotic Drug Control. It had been expected that State Senator Whitney, of Saratoga County, would be named Commissioner, but the objection was raised that he was ineligible as a senator cannot be appointed to a State office during his term in the legislature.

Influenza in South Africa.—It was stated recently by Governor-General Buxton in Cape Town that there had been 50,000 deaths from influenza during the recent epidemic in South Africa. This figure included both whites and blacks.

New York Hospitals Report Deficits.—The annual report of the United Hospital Fund, which defrays in part the expenses of free treatment in forty-six hospitals in this city, discloses a substantial increase in the number of persons able to pay for their own treatment. The total service rendered by these forty-six hospitals for the year ended September 30 was 2,513,622 hospital days, an increase of 147,672. The receipts for the year were $183,778.34, a gain of $48,688.73 over the previous year. The increase, however, in the cost of material and labor has caused thirty-six of the forty-six hospitals to close the year with deficits aggregating $391,431.36, with a result that some of the institutions have been compelled to decrease their free service.

The Medical Society of the County of New York, at its annual meeting on November 25, elected the following officers: *President,* Colonel Charles Howard Peck, M. C., U. S. Army; *First Vice-president,* Dr. Charles H. Chetwood; *Second Vice-president,* Dr. George Gray Ward; *Secretary,* Dr. Daniel S. Dougherty; *Assistant Secretary,* Dr. J. Milton Mabbott; *Treasurer,* Dr. James Pedersen; *Censors,* Dr. William S. Gottheil, Dr. Gustav G. Fisch and Dr. Herbert B. Wilcox.

An Anti-Serum for Yellow Fever.—A letter from Dr. L. Becerra, President of the Board of Health of Guayaquil, Ecuador, to Dr. J. Cueva of New York, published in *The Sun,* announces the discovery of an anti-serum for yellow fever by Dr. Noguchi, who is working with the second Yellow Fever Commission of the Rockefeller Institute in Ecuador. Dr. Noguchi is said to have isolated the microorganism of yellow fever, and to have proved its pathogenicity by animal inoculation. Following this discovery, it is said further, he has been able to prepare a vaccine with which he has immunized horses against yellow fever. The progress made with the vaccine has justified the vaccination of the troops of Ecuador that must go down from the interior to Quayaquil where yellow fever has been prevalent. The confidence that Dr. Noguchi and the authorities of Ecuador have in the serum is attested by high honors conferred upon him. The Government and the city of Guayaquil are going to make him a public expression of thanks. The national Congress is going to confer upon him the honor of the title of Doctor of Medical Science of its universities, which will be the first time such title has ever been given to a foreigner.

American Physicians Honored by French Society.—The Societé medicalè des Hôpitaux has elected the following American physicians as honorary members: Drs. Beverley Robinson, Alexander Lambert, and Simon Flexner of New York; William S. Thayer of Baltimore; Morton Prince of Boston, and James T. Chase, chief of the radiological service of the American Army in France. The following British physicians were also elected to honorary membership: Sir Bertrand Dawson, Sir Almroth Wright, Sir William Leishmann, Sir Thomas Barlow, and Sir Thomas Duckworth.

Governor of Massachusetts Urges Precautions against Diseases brought from Europe.—Governor McCall of Massachusetts has sent a letter to Dr. Eugene R. Kelley, State Commissioner of Health, urging thorough preparations for combating possible epidemic diseases which may be brought back from Europe by returning soldiers. He has also written to the authorities at Washington urging that every precaution be taken to prevent such diseases as meningitis, bubonic plague, and cholera, which are prevalent in Europe, from being brought into this country by any of our returning men.

Safety Museum Changes Name.—The American Museum of Safety has been granted permission by the Supreme Court to change its name to the Safety Institute of America. The trustees announce the extension of the institute and the enlargement of its activities for the coming year.

Dr. Henry E. Pflug and Dr. Charles F. W. Horn have been appointed temporary Police Surgeons of New York City.

Drive for Jersey City Hospital.—A campaign to raise $100,000 has been launched for Christ Hospital, Jersey City. A considerable part of this fund is needed for a new building to house the nurses. Owing to the increased demands upon the hospital from war conditions, the executive committee estimates that this is the minimum sum required to continue the work of the hospital.

Dr. Braillon, professor of clinical medicine in the Ecole de médecine et de pharmacie at Amiens, died recently from an infection contracted from a wounded soldier whom he was attending.

Dr. Paul Lucas-Championnière died recently at the age of 73 years. He was editor in chief of the *Journal de médecine et de chirurgie pratiques,* now in its 89th year, which was founded by his father in 1830. At the decease of the latter in 1870 the periodical was edited jointly by an older brother and himself, the former dying in 1913. The editorship will pass under the control of two cousins who bear the name of Lucas-Championnière and doubtless will remain in the same family indefinitely. The leading feature of this journal is the excellence and timeliness of its abstracts, which often proceed from sources quite out of the ordinary channels of information, especially recent theses and bound books. Both original and abstracted articles have always been given serial numbers, so that the total to date amounts to 25,908. During the entire course of the war the "Journal Championnière" as it is termed by its French readers, seems to have undergone no change from its ante-bellum status.

Obituary Notes.—Dr. Joseph E. Corrigan of St. Leo, Fla., formerly of New York City, died at his home in St. Leo on November 28, aged 74 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1871, and for many years house physician of Bellevue Hospital. He was one of the founders of the New York Foundling Asylum. Dr. Corrigan was forced to give up his practice in New York thirty-four years ago because of ill health. He was the father of City Magistrate Joseph R. Corrigan and brother of Archbishop Corrigan.

Dr. Linnaeus Jones Hunter, a graduate of the New York University Medical College, in 1889, died from pneumonia, at his home in New York, on November 27, aged 56 years.

Capt. Henry Guild Burton, M. C., U. S. Army (retired) a graduate of New York University Medical College, in 1869, died recently at his home in San Francisco at the age of 71 years. He was formerly clinical assistant to the chair of ophthalmology in the San Francisco Polyclinic and Medical Department of the University of California, and assistant surgeon to the Pacific Branch of the National Home for Disabled Volunteer Soldiers, Los Angeles. He entered the army as assistant surgeon in 1876, and was retired February 5, 1902.

Dr. Henry William Ross died at his home in Brooklyn on November 29, aged 69 years. He was a graduate of the New York Homeopathic Medical College, and one of the organizers of the Eastern District Homeopathic Dispensary.

Dr. JOHN P. ROWAN of Brooklyn, a graduate of the Long Island College Hospital, in 1898, and at various times attached to the staffs of the Brooklyn, St. Peter's, Holy Family, St. Mary's, and St. Catherine's Hospitals, died on November 27, aged 41 years.

Dr. JOHN G. WINKLEMAN, a retired physician of Brooklyn, died of heart disease at his home in that city, on November 24, aged 62 years. He was a graduate of the New York University Medical School in 1879 and formerly on the staffs of the Kings County and St. Catherine's Hospitals.

Obituary.

JOSEPH BIDLEMAN BISSELL, M.D.

NEW YORK.

MAJOR JOSEPH B. BISSELL, M. C., U. S. A., died at his home in this city on December 1 after a brief illness. He was home for the Thanksgiving holidays from Fort McHenry, Maryland, where he was chief surgeon, when he was taken ill.

Dr. Bissell was born in Lakeville, Conn., in 1859, and was educated at Yale College, where he was editor of the *Yale News*. He received his degree of M.D. from the College of Physicians and Surgeons of Columbia in 1883, and after serving as interne at the Charity (now City) Hospital he studied surgery in Vienna and Munich. He was professor of clinical surgery in the New York University and Bellevue Hospital Medical College, and had been visiting surgeon to Bellevue and St. Vincent's hospitals for twenty-one years. He was chief surgeon of the Radium Institute, which he established eight years ago, and was commissioned a Major in the Medical Corps of the army last July.

Correspondence.

CONSIDERATION FOR THE DRUG ADDICT.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Not only does the law for a Drug Commission in this State abrogate the confidential relations, long sustained in the courts, of professional privilege between physician and patient in the case of sufferers from drug addiction, but it compels also an equal violation of the rule of secrecy in every instance where opium or its derivatives have to be administered for any cause whatever.

On this account this law was pronounced to be unconstitutional by eminent private counsel consulted by the writer before appearing in opposition to this bill at the hearing given by Governor Whitman. This contention has been sustained since the passage of the bill both by the counsel for the Medical Society of the State of New York and by the counsel of the Medical Society of the County of New York.

Failing in every effort to protect the rights of the patient and the physician and with no apparent endeavor on the part of the organized medical bodies of the State to test this matter in the courts, a set of resolutions were presented to the Medical Society of the County of New York in the hope that the scientific laboratory and clinical investigation of drug addiction therein proposed might afford some measure of relief to an otherwise calamitous condition of affairs both to the physician and the patient. This presentment was based upon the findings of the Committee on "Narcotic Drug Investigation" of the Medical Society of the County of New York made and adopted March 25, 1918, in which it was stated that "After carefully considering the matter of drug addiction we have come to the conclusion that the addict is entitled to the same medical care vouchsafed any other diseased or afflicted person." The resolutions in question were presented and adopted unanimously at the regular meeting of this Society on November 25, 1918.

NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE MINISTRY OF HEALTH BILL—ROYAL AIR FORCE MEDICAL SERVICE—PROPHECY AND INFLUENZA.

LONDON, November 8, 1918.

ON Thursday, November 7, the long expected Ministry of Health Bill was introduced by Dr. Addison. The bill proposes to establish a Ministry of Health and a Board of Health to exercise in England and Wales and Scotland respectively powers with respect to health and the local government connected therewith. The main purpose of the new measure has been accurately indicated in these columns more than once. It is to bring together under one ministry the chief departments dealing with the health of the people, so that we should no longer have the comical position now occupied by official medicine, namely, that authority resides (mainly though only partly) with the Local Government Board, most importantly with the Board of Education and the National Insurance Commissioners, but also with the Home Office, the Foreign Office, the Statistical Bureau at Somerset House, and even the Privy Council. The bill gives the new Ministry powers to bring under one roof the medical inspection and treatment of school children, the health duties of the Ministry of Pensions with regard to sick soldiers, the powers of the Home Office with reference to lunacy and mentally deficient, as well as the care and treatment of the impoverished sick and infirm now administered as part of the Poor-Law under the Local Government Board. With regard to Scotland the Bill brings together in precisely the same way as in England the different health services under a Board of Health responsible to the Secretary for Scotland, but the proposals of the Bill are not extended to Ireland, in view, said the optimistic Dr. Addison, of the belief that "Ireland would soon administer her affairs for herself." There was opposition on the first reading of the Bill, though the opposition did not go to a division, because the measure takes away, or appears to take away, from the National Insurance Commissioners their right to deal with questions of disease and ill-health, and this position will have to be made particularly clear on the second reading or in the committee stage. The National Insurance Commission represents clinical as opposed to preventive medicine, in relation to the more important third of the community —probably the proportion could be put higher, and there must be no doubt whatever under any Minis-

try of Health that this great block of State therapeutics is not altered save for the better. At the present moment the National Insurance Commissioners command the services of the Medical Research Committee, although the work of that Committee has been largely directed for the past four years in assisting to carry on the war. In the future the work of the Committee must be for the good of the State and must not work solely for any section of the community, however large and important. Lastly, those who anticipated any vast general scheme for erecting medical practitioners into a State Service will not find in the measure anything of the sort; but although a great many of their ideals will not be capable of accomplishment at once, there is nothing to prevent a State system of medicine arriving in the reasonable course of evolution.

The important post of Director General of the Royal Air Force Medical Service has been offered to Colonel Fell, a very distinguished and capable officer of the Royal Army Medical Corps, who is understood to desire to administer the service under the enlightened scientific system laid down by the Watson Cheyne report already summarized in a previous London letter of which I remind your readers.

On publication in *The Lancet* of the conditions of the Royal Air Force Medical Service evidence was obtained that those conditions, as embodied in the Watson Cheyne report, had been received with great satisfaction by the medical profession, as representing an improvement from the scientific point of view upon any terms hitherto offered to the medical profession when engaged on naval, military, civil, or administrative work. The partition of medical work of the Royal Air Force into two main branches, one having the care of the effective personnel and the other of the non-effective made proper room for the allocation of the medical officers to occupations for which they were fitted. The care of the effective personnel could under the scheme be undertaken by officers whose work had lain on the hygienic and preventive side of medicine, while it was here that the psychologist had his fruitful field of activity, by taking into consideration the physiological, but also the psychological, attributes of the candidate. The officers in charge of the effective personnel could be selected in special directions to make all the necessary investigations of the respiratory and circulatory systems of the flying officer, his special senses and visual reflex; while those officers who had studied the psychology of medicine could make proper inquiry into the "flying temperament," now recognized as an asset of incommensurable value. The fifteenth general condition runs as follows: Promotion to ranks above that of Captain in the R. A. F. Medical Service will be by selection to fill vacancies in the establishment. This means that the officers in the Royal Air Force Medical Service would be intrusted with subdivisions of medicine or surgery where they had shown special knowledge while a system of special merit, promotion, and pay would be instituted.

Early in August the Medical Research Committee issued to the medical press the following statement:

The pandemic of influenza has not spared any single part of Germany. The clinical course does not seem to differ from that run by the disease in this country. Relapses and fatal pneumonias are particularly noted. The clinical picture is declared to be identical with that of the last pandemic of 1889. A very striking observation has been brought forward and generally confirmed at a special meeting of the Munich Medical Union on July 9—namely, that persons under thirty years of age mainly fall victims to the disease; this was explained by a survival immunity in the elder generation. The meeting considered all the aspects of the epidemic on the basis of the hospital and university material of Munich. Pfeiffer's bacillus has been found but exceptionally; streptococci, and occasionally pneumococci, were recovered from the sputum, organs, and also blood of the patients. Similar findings were recorded in 1889, and thus the present results were in "keeping with the precedent." Pfeiffer's bacillus had not been found until 1892, although it should have been impossible to overlook it in 1889; thus it may be that it will yet turn up in due course. The editors of the *Deutsche medizinische Wochenschrift* have addressed a circular inquiry to all the leading bacteriologists in Germany requesting enlightenment as to the results of their laboratory investigations. Pfeiffer himself had reserved his final opinion as to the relationship of the pandemic with those of 1889 and 1891-92. He had not examined a sufficient number of cases at Breslau, but found his bacillus in some, while failing to recover it from others, and was still investigating the causes of this discrepancy. Gruber answered from Munich very simply: "Influenza bacilli not found hitherto—investigations proceeding." Ulrich Friedemann, who is in charge of the infectious wards of the Virchow Hospital of Berlin, expressed his belief that the symptomatology and complications of the epidemic correspond exactly with those described in 1889-90. He had not found the Pfeiffer's bacillus, streptococci and pneumococci being the most common agents of the complicating pneumonias. The influenza bacillus may be evading capture on account of faulty method of inquiry, yet on the other hand the possibility must not be overlooked that there may be epidemic diseases clinically resembling influenza of which Pfeiffer's bacillus is not the agent. Uhlenhuth has so far reported from Strassburg the same contradictory results as those of Pfeiffer. Kolle reported under date of July 18 from Frankfort his failure to detect Pfeiffer's bacilli in any of the few cases which he had thoroughly examined. In practically all cases there were found, however, large numbers of a Gram-positive coccus—often in a pure culture or in symbiosis with pneumococci. The diplococcus tended to develop involution forms and to grow in very long chains in the condensation water. He regards them as agents of a secondary infection in the "Spanish disease," which to his mind may not be identical with the pandemic influenza of 1889-1893. The finding of this pleomorph Gram-positive diplococcus is very interesting in view of the observations of Rosenow and his pupils in the United States.

This statement was published in *The Lancet* and the British *Medical Journal*, the latter paper sagaciously adding that the Committee, from whom the statement had been received, would be glad to receive further information on the subject. It is quite clear that the résumé of important communications on the subject of influenza included an indication of the likelihood of the onset of secondary waves of the epidemic in the Autumn. Moreover, there was contained in the résumé what almost amounted to a prophecy that those secondary waves would be more severe in character than the primary waves of the Spring. It is an unfortunate fact, however, that no practical attention was paid, so far as can be ascertained, to the prophecy; indeed, the fact that the prophecy had been made appears to have escaped the notice of the British clinicians and sanitarians. The preventive medicine of the country

is watched over and controlled from the Local Government Board, and while the epidemic was at its height a valuable circular was issued from that Board pointing out the anxiety of the position. But at that time the epidemic was at its height and to recommend certain general methods of prevention was belated. It stared all men in the face that the circular, which would have been exceedingly valuable two months previously as a warning, was behind its date as a therapeutic measure, for it gave the community details of the dangers which were already upon them and with which they were only too conversant. There is no doubt that prescience was not displayed in the exact quarter in which it might have been expected, but we cannot find that the gift of prophecy was very much displayed by any one outside the Board except the Medical Research Committee, and the warnings of that body fell upon deaf ears.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

INFLUENZA IN PARIS—CHANGES IN THE MEDICAL CORPS PERSONNEL—GAMES FOR SOLDIERS.

PARIS, November 4, 1918.

ACCORDING to the official statistics during the past week, there were 1,944 deaths in Paris, as compared with 1,465 in the previous week. The average figure at this time of the year is 721. Of the 1,944 deaths, 880 were put down to influenza. Precautions to be taken to prevent the spreading of the influenza epidemic are given in a report issued by the Epidemic Committee of the Seine Department. The following points are included in the report: Influenza may be transmitted from a person suffering from the complaint, when speaking or coughing, or even by touch. Contact with those who are ill should therefore be avoided. Persons who are taken ill should be isolated, if not possible at home by being sent to a hospital. Those in attendance need not keep at too great a distance. The objects for the patient's use should be disinfected. Attendants should wash their hands and rinse their mouths each time after looking after the patient. If the case is serious they should use a respirator over the mouth and nose. Gatherings of people both in the open and indoors, such as in churches, theaters, big shops, and trains, should be avoided and personal cleanliness should be strictly observed, especially as regards the mouth and hands.

According to information from medical officers, influenza, so far as the troops are concerned, is confined to the ports, and there the cases are being handled so carefully that there is practically no danger of its spreading to the troops at the front.

Major General Merritte W. Ireland, recently appointed surgeon general of the United States Army, to succeed General William C. Gorgas, retired, came to France as General Pershing's choice for chief surgeon of the A. E. F., and has accomplished excellent work in that capacity. Though his aides are congratulating him on his appointment, he regrets leaving France at this time. Col. Walter D. McCaw has been appointed chief surgeon of the A. E. F., pending official confirmation from the War Department. Colonel McCaw has had wide experience in medical administration, having been in charge of sanitation of troops on the Mexican border prior to his coming to France. Brig.-Gen. Jefferson Randolph Kean, who has been closely associated with General Ireland at the chief surgeon's headquarters, will, it is expected, continue in the same capacity in Washington. Maj. Thomas Hurley of the United States Army Ambulance Service with the French Army, is to-day receiving the congratulations of his fellow officers upon his promotion from a captaincy in the Medical Corps. He will leave next week to be the official liaison officer for the Ambulance Service.

One of the most difficult problems that the Y. M. C. A. is meeting in France is that of finding games suited to all sorts of conditions. The normal American sporting calendar is rich enough in good competitive athletics, but many of the games that flourish at home are not available in some of the areas in which America's soldiers are operating. Baseball and football, for example, are wonderful games, but they require skill, and that takes time to acquire, plenty of room, a big level field, a considerable amount of equipment, and the number of men that may play at a time is limited to eighteen and twenty-two respectively. Also it is necessary to have fairly expert officials in order that these contests be conducted successfully. What the army needs in many cases is a game that a large number of men play at one time, that requires a minimum of paraphernalia, little space, and that can be learned quickly and well enough to be enjoyed. Such a sport the Y. M. C. A. physical experts believe has been found in "Y" ball, a new pastime evolved this summer in the Red Triangle training schools in America, and now being played with great success by the Army in France. This game is a modification of indoor baseball. For the purpose to which it is put it has certain advantages over the regulation brand of that sport. As many as thirty men can play on a side. Every batter is practically sure to hit the ball, as it is merely tossed to him by one of his own side without "anything on it." The rules are very simple and the umpire need not be endowed with the wisdom of Solomon nor the eyesight of a hawk to be a thorough success. Anybody can learn to play this game in a few minutes. The action is constant and lively.

9. Carbolic Acid in Tetanus.—D. Delfino reports a case of tetanus in which no result was obtained by the injection of antitetanic serum, but in which recovery followed the injection of 2 per cent. phenol in

sterile oil. Altogether the patient received 35 c.c. of the phenol, the dosage being 10 c.c., 15 c.c., and 10 c.c. on three successive days. A dermatitis developed which practically involved the whole face, the urine became scanty and cloudy and contained albumen and phenol; patient gradually became relieved of symptoms and made an uneventful recovery. Diagnosis in this case was not confirmed by bacteriological examination, but the patient was seen by at least ten physicians, who all concurred in the diagnosis of tetanus. The treatment of tetanus by phenol was tried with good results about twenty years ago by Baccelli, who used 1 to 2 per cent. carbolic acid in sterile oil, giving injections of 2 to 4 c.c. subcutaneously, and increasing the dosage finally to 75 c.c. daily. Maragliano claims a number of cures as a result of treatment with carbolic acid alone. The author states his intention of trying the remedy in other cases, since phenol was manifestly the cause of recovery in the case under consideration.

1. Multiple Infections: A Study of the Relation of One Infection to Another.—William W. Duke points out (1) that when a person has several infections each may increase the severity of the others, whether due to the same or different microorganisms; (2) that acute exacerbation of one chronic infection may stir up other apparently latent infections into activity; (3) that the removal of one infection may under favorable conditions be followed by spontaneous healing or improvement in others; (4) that if minor infections are properly taken care of, those that appear more serious may yield more easily to treatment; (5) that chronic sepsis exerts a serious influence on the course of tabes dorsalis, and its removal is frequently followed by amelioration of the symptoms of this disease. The author cites cases in which the eradication of chronic sepsis in patients suffering from syphilis of the nervous system has resulted in marked improvement; he states, in fact, that as a therapeutic measure the removal of chronic sepsis in tabes dorsalis ranks in importance barely second to specific medication. The problem of multiple infections and the relationship that one infection bears to another may best be described under the terms allergy, protein sensitization, and anaphylaxis. Duke notes that of the microorganisms, the tetanus and diphtheria bacilli are the only ones that produce a true toxin. Allergy and its effects are well illustrated by the action of tuberculin, with the local, general, and focal reactions. The well-known principles of these reactions are true of infection in general and furnish an explanation of many interesting phenomena, *e. g.* why with the onset of a new infection, signs of irritation and inflammation may appear within a few hours at remote points; why an attack of typhoid renders a person sensitive to the protein of the typhoid bacillus, etc., etc. Whether or not this explanation applies in cases in which different microorganisms are present is open to question, since sensitization against the protein of an infecting organism is believed to be more or less specific. However, the fact is indisputable that infection with one microorganism may lower the resistance against other microorganisms to a degree that is by no means negligible. Apparently there exist two types of immunity—a specific and a non-specific immunity. The latter has been made use of by Miller and Lusk, Jobling and Petersen, and others, who have injected alien protein of different types (including killed typhoid bacilli) in the treatment of arthritis and other infectious diseases, with striking results. The reactions produced by the injection of alien proteins are often very similar to reactions that follow inoculation with the specific organism that causes the person's disease. It is not inconceivable that repeated inoculations with a non-specific virus might cause repeated reactions in inflammatory lesions due to other organisms and in this way do harm and cause an exacerbation of the disease. It is possible that one infection may exert a deleterious influence on lesions caused by other microorganisms, which might in part explain the cure of one infection by the removal of another infection in no wise related to it. Whether or not the explanations given are correct, a consideration of the relationship between infections often assists in the practical handling of the situation.

5. Supplement to a Note on "Acute Yellow Atrophy" (?). Ernest Glynn.

1. An Address on Spirochaetosis Icterohaemorrhagica.—Major-General Sir Bertrand Dawson describes first of all the spirochaeta icterohaemorrhagica. This organism was first described by Inada and Ido in 1914; it varies in length from 4 μ to 25 μ, with an average of 8 μ to 9 μ; the ends are sharp and pointed and in many cases hooked. Terminal flagella ending in circular knobs have been described. The spirochete was first cultivated by Ito and Matsuzaki, who, following the method of Noguchi, replaced the kidney of the rabbit by that of the guinea pig. Martin and Pettitt noted that an antiserum for spirochetal jaundice agglutinated the spirochetes, and the sera of convalescents was found also to possess this power of agglutination, and since the organism can be grown with ease, we have here a valuable diagnostic test. The clinical manifestations of the disease are usually sudden onset with shivering, head and body pains, great prostration, vomiting and diarrhea. Temperature, 102° F. or higher. The conjunctivae become injected and herpes, often hemorrhagic, appear on the lips in about 40 per cent, of cases. Bleeding occurs in severe cases; a slight hemoptysis early in the disease is a valuable diagnostic sign. Hemorrhage often precedes jaundice, which usually appears on the fourth or fifth day, but may be as early as the second or as late as the seventh day, and reaches its height about the tenth or twelfth day. Constipation is marked and stools may become clay colored. Usually there is tenderness of the upper abdomen. Tongue is furred and brown, and liver frequently enlarged. In severe cases there are evidences of acute bronchitis; respiration may rise to 28 or 30, and in fatal cases may resemble that met with in uremia. Pulse rate of 75 to 85 is usual. Systolic B. P. is about 120 mm. Early weakness and prostration are characteristic of the disease. Urine contains bile in abundance, which may persist for four or five weeks; albumin is usually present, and casts are common. Some French authors lay stress upon renal insufficiency. In acute cases, an irregular type of pyrexia persists for ten to fourteen days and ends by lysis. There may be a secondary rise of fever about the

beginning of the third week, which is difficult to explain. Convalescence is slow, but recovery is complete. From the morbid appearances of two fatal cases cited, it would appear that in some instances the infection localizes in the duodenum. In others, definite changes resembling those seen in subacute yellow atrophy are seen in the liver. Observations seem to show that the disease falls with varying force upon the liver, the changes varying from slight deviation from the normal to extreme disorganization. Changes in the kidneys also vary and in some cases are so marked as to approach necrosis. The spleen and pancreas show no departure from the normal, but peritoneal, subpleural, and subpericardial hemorrhages are common. Hemorrhages in the substance of the lung may resemble in size and constituency those met with in mitral stenosis. The disease resembles syphilis, another spirochetal infection, in that the same organs are not always attacked. The jaundice is caused by obstruction of the outlet of the common duct, or by interference with the drainage of the bile within the liver. Where there are no definite changes in the liver and no swelling of the duodenum, jaundice is absent. No evidence of blood destruction has been found in spite of repeated examinations. Comparing acute yellow atrophy and spirochætosis icterohæmorrhagica, a striking resemblance is found, and Dawson believes that what is styled acute yellow atrophy in the post-mortem room is the fullest anatomical expression of a destructive process which may be caused by several agencies, the *Spirochæta icterohæmorrhagiæ* among others. Of the laboratory animals the guinea pig is the most susceptible to the disease and in this animal pathological changes are very characteristic. The spirochete, which is found with difficulty in man, is abundantly present in the guinea pig, in the blood, the liver, the kidneys, the suprarenals, and the urine; they are excreted in the urine, feces, and bile, all of which are infective for the guinea pig (and man). Japanese and French workers have found the urine of patients infectious for guinea pigs, but Stokes and the author himself have failed to transmit infection in this way. The *Spirochæta icterohæmorrhagiæ* is found in the kidneys and urine of rats and Noguchi has shown that American wild rats harbor this organism and has also proved that the American, Japanese, and Flanders strains are identical. Coles found the spirochete in nine out of 100 rats examined in England. The disease is conveyed to man through water fouled by infected urine of rats; in Flanders the disease has been more prevalent in wet than in dry trenches and has appeared in endemic form. The evidence shows, therefore, that (1) this spirochete can be found in the peripheral blood stream of patients suffering from the disease; (2) injection of infected human blood into the peritoneal cavity of the guinea pig will produce a characteristic fatal disease in that animal, in whose tissues the spirochetes are present in large numbers; (3) the spirochete has been isolated in pure culture, and inoculated from such culture the guinea pig contracts the disease; (4) the disease has been produced in man by accidental inoculation from an infected guinea pig; (5) after the first fortnight of the disease the spirochete may be found in the patient's urine, and in the third week of the disease the patient's serum agglutinates the spirochete. The difficulty in diagnosis lies in the fact that in the early stages of the disease the symptoms may only be those common to several diseases and as the blood of the patient is only infective for the first few days (after the fifth day the chances of a positive result diminish and after the eighth day are few), and the jaundice does not usually appear until the fourth or fifth day. The opportunity of guinea pig inoculation may therefore easily be lost. In such event urine inoculation should be tried with a chance of success. Direct examination of the blood is not of much value, since the spirochetes are only present in the circulation for the first few days and even then only in scanty numbers. There remains the demonstration of spirochetes in the urine where they appear about the ninth and reach their maximum about the fifteenth day, disappearing about the end of the fifth week. The possibility of confusing the organism in question with urethral spirochetes of the meatal and refringens types may be eliminated by washing the glans and meatus and catching the middle portion of the urine in a sterile flask. Moreover, in healthy and in most sick people spirochetes are not excreted by the kidney, whereas in spirochætosis icterohæmorrhagica the causal spirochetes are always excreted in this way; in some cases of fever of unknown origin (P. U. O.), but excluding enteric, spirochetes other than those of spirochætosis icterohæmorrhagica are excreted.

4. **Observations on a Small Localized Epidemic of Influenza, with Special Reference to the Incubation Period.**—Majors Michael G. Foster and H. Anstey Cookson report a small series of cases (nine in number) of influenza observed in a surgical ward of the general hospital in France. There is no doubt in the minds of the authors that all these cases were influenza, both from positive bacteriological results obtained in two of the cases and from clinical observations. The following symptoms were presented by one or other case, and the duration of the illness was either long or short: (1) septicemia, (2), coryza, (3) bronchitis, (4) bronchopneumonia, (5) otitis media, (6) body pains, etc. In all these cases the incubation period was about forty-eight hours, and the cases in which possibilities of accurate observation were greatest were those which approximated most closely to a forty-eight-hour period. These observations illustrate two factors in the spread of influenza: (1) The narrow radius within which infection takes place; there were twenty-six beds in the ward and in the nine cases which occurred the infection spread from one bed to the next in rotation and was apparently stopped upon reaching empty beds which limited the cases on either side, the only exceptions being two cases which occurred on the opposite side of the ward. (2) The shortness and apparent punctuality of the incubation period. Both these factors help to explain the rapid spread of epidemic influenza.

1 Purulent Bronchitis Complicating Measles and Rubella. Lt.-Col. W. M. Macdonald, Major T. R. Ritchie, Lieut. J. C. Fox, and P. Bruce White.
2 The Differential Diagnosis of Scarlet Fever, Measles, and Rubella. Lt.-Col. J. S. Warrack.
3 Incubation Period of Influenza. Peter Macdonald and J. C. Lyth.

3. **Incubation Period of Influenza.**—Peter Macdonald and J. C. Lyth give the incubation period of influenza as forty-one hours (minimum), with a maximum margin of four hours, a computation based on personal experience. These authors both traveled from 5.30 P. M. to 9.30 P. M. on October 3 last with an officer who was coughing and sneezing and who informed them that he had had influenza for several days. On October 5, between 2 and 2.30 P. M., both of these observers suddenly developed typical attacks of influenza, both commencing with laryngitis. In one case the attack was mild, in the other more severe. The wife and two children of the latter also developed the disease, the first symptoms appearing suddenly about 2 P. M. on October 7. As infection probably did not take place until a few hours after the first symptoms observed by the author in his own case, the period of incubation was approximately the same as in the case of the authors themselves. A culture taken from the posterior nares of one of the authors on October 10 showed colonies of Pfeiffer's bacillus and the *Micrococcus catarrhalis*.

2. **Antirabic Vaccination in Cuba.**—J. Santos Fer-

nandez and F. M. Fernandez give a detailed description of the work of the Anti-Rabic Laboratory of Havana, that was established since 1887, or previously to any other in America. During that time 5,188 persons have been treated, and of these thirty-six have died from rabies. The percentage of mortality is 0.65. Dogs were the chief causes of infection, 4,712 persons having been bitten by dogs; next followed cats, 429 in number; horses bit nine persons, oxen, goats, and mules have six cases to their credit each; pigs, five; rats and rabbits, three; monkeys, two; squirrel, one; the ass one; five cases were inoculated by human patients. The method followed is the same as that of the Pasteur Institute of Paris.

Constitutional Hypersensibility and Bronchial Asthma.—A. Besche offers a study of the case of a male having a hypersensibility in relation to horse-manure. This idiosyncrasy only became evident after injection of antidiphtheritic serum at the time of equitation or simply when the subject partook of sausages containing horseflesh. The blood of this interesting subject, when injected into a guinea-pig, caused the little animal to be hypersensitive to horse serum after the lapse of forty-eight hours. The anaphylaxis of the subject was also local. If he brought his finger, which had come in contact with a horse, in contact with the conjunctivæ the result was a mild edema of the mucosa touched. The writer has met with this ocular reaction in eleven cases of "equine asthma" that he has had under observation, and in yet another subject asthma occurred when a cat had been the pet. Certain asthmatic patients incriminate other domesticated animals as etiological factors of their paroxysms. Besche recalls the danger of antidiphtheritic injections in subjects predisposed to accident from equine anaphylaxis.

Death in Diabetic Coma Following a Traumatic Lesion of the Tail of the Pancreas.—K. Rochs has had a soldier under observation with a penetrating wound of the left flank from an exploding shell who was cachectic with a hyperglycosuria, acetonuria, and diacetic acid. At autopsy, the writer found traces of a missile track involving the splenic region and tail of the pancreas. The latter, viscous in its entirety, was the seat of an inflammatory process already arrived at chronicity, made evident by fibrous transformation and degeneration of the parenchyma. Death in coma occurred three months and a half after receipt of the injury.

Nerve Suture.—W. Spielmeyer, out of a total of 280 cases of nerve suture which were followed, selects 100 in which the postoperative time expired was not less than six months. He classifies the cases as follows:

	Successful	Improvement	Unsuccessful
32 cases of the radial nerve	11	11	10
12 cases of the ulnar nerve	3	1	8
16 cases of the median nerve	4	4	8
8 cases of the superior plexus	2	3	3
9 cases of the peroneal nerve	2	4	3
2 cases of the tibial nerve	0	2	0
21 cases of the sciatic nerve	1	11	9

The writer considers as successful the return of total motricity, even if still weak in certain territories of the nerve. He notes as improvement a marked return of the functions. He likewise notes the more favorable results obtained in suture of the radial, but the sciatic does not give such poor ultimate results as one might infer from the above table, because the number of cases noted as improved were, in reality, almost successful from the writer's viewpoint, although most American surgeons would not accept his reasoning as exact, and, all things considered, the total result, which only concerns direct suture, cannot be looked upon as joyful. Studying the histological modalities of regeneration, the writer defends his conception of proliferation and transformation of the cells of Schwann. He shows with microphotographs that total division of the nerve, followed by a cicatrix, does not of necessity constitute a permanent obstacle to regeneration. The fibrillæ force their way through the cicatrix in the most varied ways and finally end in a perfect functional recovery. A very early operation after division of a nerve is not logical, since regeneration takes place quite as well during the second three months as during the first few weeks following the injury. But the writer hastens to add that the clinical waiting time should not be prolonged beyond the lapse of six months. As to secondary operations in unsuccessful cases, the writer advises, as a general rule, to allow three years to elapse, as this time may be requisite in order to allow the results of the first operation to make themselves manifest. As to operative technique, Spielmeyer is of the opinion that actual apposition of the divided nerve is not essential. In cases of diastasis Berthe's procedure (nerve graft from a cadaver) is to be highly recommended. When a portion of nerve from a corpse cannot be had, uniting two nerves can be realized by incising the remaining intact nerve and bringing the flap over with its suture to the peripheral nerve.

Widal's Reaction: Can It Be Employed in Subjects Vaccinated Against Typhoid?—W. Liess says that coagulation of the paratyphoid bacillus accompanies more than 50 per cent. of vaccinated and unvaccinated cases of typhoid. This coagulation is absent in subjects who have been vaccinated for more than eight weeks and who have not developed typhoid. This property may render the Widal reaction applicable in vaccinated subjects.

Stiff Knee Without Ankylosis Following Wounds of Warfare and Its Operative Treatment.—M. Katzenstein says that when a joint is stiff and not due to bony ankylosis, it may be the result of a mechanical cause or of a reflex action set up by the lesion, with pain on movement. The usual treatment of these cases has been rapid or progressive mobilization, but this procedure offers the drawbacks of the lighting up of a latent infectious focus or the production or accentuation of anatomical lesions. Katzenstein has resorted to operative treatment. After division of the ligament of the patella, the latter is retracted upward and the joint freely exposed. He next proceeds with the abrasion of the tissues which interfere with the movements, such as irregularities of the joint cartilaginous surfaces, ligamentous or fatty proliferations. The bone defects are covered in by fat or cartilage flaps derived from the joint itself. The patients operated on by the writer obtained movable joints and in no case did suppuration occur, regardless of the fact that the joint was closed at once with sutures, followed by mobilization a few days after the operation.

Extensive Xanthomatosis in a Case of Intense Diabetic Lipemia.—E. Hoffmann records the case of a soldier, aet. twenty-five years, with diabetes (60 per cent. sugar), who presented a multitude of small xanthomatous tumors, particularly over the extensor aspect of the arms and legs, on the face, buttocks, and prepuce, which resulted in phimosis. The tongue and conjunctivæ were not involved in the process. The blood was whitish and cloudy, this being due to droplets of cholesterin in suspension. There was also a marked lymphocytosis. Histological examination of the tumors showed the classical cells of xanthoma with deposits of a birefringent substance. A pleural collection which developed was also found very rich in fat. At autopsy, Ribbert discovered a striking paucity of the endocrine islands of the pancreas. It is to be noted that death was preceded by fever as well as by a marked decrease of the lipemia, a fact that Hoffmann explains by a more complete combustion resulting from the fever.

October 5 1918.

The Leucocytic Formula as a Diagnostic Means in Infectious Diseases.—H. von Jagic wishes to replace the term "large mononuclear" by that of "monocyte," including the transitory forms. These "monocytes" and myelocytes arrested in their development and degenerated. The presence of myelocytes in the circula-

ting blood has little diagnostic value. The morphological changes of the fully developed elements are more important; swelling of the nuclei of the multinuclears in various infections and poor staining of the granulations in the same circumstances. The terms "lymphocytosis" and "lymphopenia" should be accepted in the strict sense and not in the percentage of white cells. The writer offers some considerations of a technical kind before passing to the question of the "blood formula and constitution." The cause of the changes of the leucocyte formula are not always to be attributed to the disease, since the soil upon which it develops may play a large determining part.

Neosalvarsan in Gonorrheal Cystitis.—Von Baar reports good results, particularly in "vagotonic subjects," as described by the Vienna school.

Correspondenz-Blatt für Schweizer Aerzte.

August 17, 1918.

Differentiation of Paroxysmal Tachycardia.—Roth states that while at first sight this should be easy, there are in reality different conditions which give rise to the same symptoms, so that interpretation is required. In its absence there can be no rational therapeutics. In the first place, the heart with this behavior may be normal or diseased. Paroxysmal tachycardia is closely allied to extrasystoles, the mechanism of both phenomena being related. The structures of the heart involved in both are the sinus, auricle, atrioventricular nodes and certain portions of the ventricle. The author goes so far as to state that the two phenomena are virtually one (*i.e. in the extrasystolic form*), not only in mechanism but in etiology. It is known that in arrhythmia perpetua paroxysmal tachycardia cannot be elicited (with the possible exception of ventricular or atrioventricular attacks of very rare occurrence). Disturbances of conduction stand in some relationship to paroxysmal tachycardia. Total atrioventricular dissociation prevents the development of ventricular tachycardia outright. The foregoing data show merely where the impulses are elicited, but throw no light on the casual factors. The nervous factors are vagus paralysis, accelerator stimulation, or both combined. The essential factor, however, is pathological irritability of the cardiac muscle fibers. The importance of the nerve mechanism in these attacks is shown by the presence of psychogenic forms. To better illuminate these conditions the author cites cases: A soldier of twenty-two years was found to suffer from palpitation. Over a year previous he had had follicular tonsillitis. Examination when free from paroxysms revealed nothing special. During a paroxysm he exhibited no dyspnea nor were there any evidences of dilatation. There was marked venous pulsation in the neck. The pulse was 225. Compression of the eyeball brought about a notable reduction in frequency, which held until the attack passed off. The patient ultimately recovered from these crises. From an analysis of polygrams under various conditions, including the use of atropine and adrenaline, the author decided that the tachycardia originated in the sinus. Of four other cases given in detail all were also examples of sinus tachycardia, which is therefore of common occurrence. The first three cases were typical, the others atypical. In the former sudden attacks of over 200 frequency, with feelings of anxiety and subjective palpitation, first heart sound audible at a distance and recurrent attacks constitute the picture.

Boletin de la Asociacion Medica de Puerto Rico.

June, 1918.

Dengue and Its Prophylaxis.—Figuera states that dengue is a malady of tropical and subtropical regions, contagious and of unknown causation. The symptoms are pyrexia, arthroneuromuscular pains, and a peculiar exanthem. It has had many popular designations, including those bestowed upon it in countries not commonly visited by it. But while in Spain it was known as the mild or gentle sickness; in Philadelphia it once received the designation of "break-heart" fever from the intense prostration which followed it. The Spanish name apparently meant nothing beyond the fact that there was no mortality; not that suffering was absent. At the present time its geographical incidence is given as follows: the Mediterranean regions of both hemispheres, from which it proceeds into the interior; the tropical and subtropical regions of Asia; the Malay archipelago. It is believed to be endemic in Egypt, Arabia, India, and to some extent in Central America and the Antilles. According to Bancroft the cause is an ultravisible germ and some intermediate host is necessary for its propagation. In Puerto Rico the mosquito is regarded as the host and there is good authority for this belief. Hospital patients protected from mosquitos have been seen to escape infection. The disposition to attack every one without respect to person is marked in dengue. The infection fairly radiates in all directions and this suggests mosquito propagation. The spread is also very rapid. The epidemiology agrees fairly well with that of yellow fever and differs radically from that of influenza. It respects high altitudes, which once more suggests a mosquito-borne disease. Even at a height of 600 meters, as in the Reunion Islands, the disease was unable to diffuse itself. It is eminently a disease of the litoral. The disease confers no immunity and the patient may be attacked two or three times in one epidemic. When the disease first appears in a community one has to exclude yellow fever. The course of the malady will soon do this. From grippe it is distinguished by the absence of catarrhal symptoms and by the peculiar exanthem. The latter appears on the extremities—hands and feet—and also on the trunk, neck and limbs and head. An initial redness is succeeded by fine papules which undergo desquamation and suggest scarlatina, which, however, seldom flourishes in the tropics. These scales have been regarded as conveying the contagion. In regard to prophylaxis one can seek a higher altitude, protect against mosquitos and, to be on the safe side, use antiseptics on the skin, as in Milnes's treatment of scarlatina.

Journal d'Urologie Médicale et Chirurgicale.

August, 1918.

Renal Lithiasis in a Urological Center for Troops.—Rochet and Boulouneix describe the cases of renal lithiasis which occurred at the Urologic Center for the XIV Region during the triennium, March, 1915-March, 1918. The total number was thirty-four, each case being given in detail. Infection was present in all but five cases. There were twenty-nine cases of renal, two of renoureteral and three of ureteral stone. In six cases the lithiasis was bilateral. The number of operative cases was ten, of which three were bilateral. The authors think thirty-four cases a good many, although one might readily get the impression that renal lithiasis is a rarity in men leading the lives of soldiers. These cases were largely of the silent type without history of renal colic, etc. The symptom which brought them to consultation was either hematuria or pyuria, or stone in the bladder. To explain the formation of stone and subsequent infection the authors cite the predominance of animal protein in the regimen, the hardships and the rough life on wagons and horseback. Infection is indicated by the supervention of pyuria. The general condition of the essentially robust men was not compromised by the calculosis, although the affected kidney was rendered partly insufficient in some of the material. The operation was always pyelotomy and it was impossible to state whether the function of the kidneys was completely restored thereby.

Third Reunion of the Chiefs of the Urological Centers.—This meeting, which was held in the autumn of 1917, discussed jointly the following subjects: Management of those with traumatized kidneys and ureters at the front and rear, and autoplastic procedures applicable to fistulæ of the urethra. Under the first head the following individual questions were debated: Contusions of the kidney, wounds of the kidney, operative intervention, wounds of the ureter, and military value of soldiers with old kidney lesions. The following were among those present: Cathelin, Luys, Pousson, Marion, Legueu, Rochet, Escat, Pasteau, Desnos, Le Fur, Nogues, André.

Book Reviews.

THE PHYSICAL CHEMISTRY OF THE PROTEINS. By T. BRAILSFORD ROBERTSON, Ph.D., D.Sc. Professor of Biochemistry and Pharmacology in the University of California. Price, $5.00. New York: Longmans, Green & Co., 1918.

THIS work was originally published in Germany, some six years ago. It now appears in English, with suitable additions, in the valuable series of monographs on Biochemistry issued by the same publishers. Among the new material which has appeared since the first edition was published, and which the author has incorporated in the present volume, may be mentioned Van Slyke's method of determining free amino groups, Pauli's work on the combining capacity of deaminized proteins, the work of Schmidt and of Ugglas on the compound proteins, Proctor's work on the swelling of protein jellies, the work of Reichert and Brown upon the crystallography of hemoglobin, and that of Dabrovsky upon the molecular volume of proteins dissolved in water and in solutions of coagulating salts. The present edition has been almost entirely rewritten, and at the end of each chapter there is a carefully edited list of the books and papers and literature in general bearing on the subject of the chapter; this bibliography has been brought down to the middle of the year 1917. The book is not one of general interest to the practitioner of medicine, but to the student of physical chemistry and of the biological sciences the work will appeal as a reference book in which may be found much of the recent work on the chemistry of the proteins which has hitherto been scattered widely throughout the medical, biological and chemical literature. Proteins and their derivatives are now being used in a number of important industries, their use here being attributable to their peculiar physico-chemical behavior.

A MANUAL OF OTOLOGY. By GORHAM BACON, A.B., M.D., F. A. C. S. Assisted by TRUMAN LAURANCE SAUNDERS, A.B., M.D. Seventh edition. Revised and enlarged. New York and Philadelphia: Lea & Febiger, 1918.

THIS is the seventh edition of Dr. Bacon's well-known manual, the previous publication bearing the date 1913. According to the Preface, Dr. Saunders has revised the chapters on adenoid growths, enlarged tonsils, submucous resection of the septum and suppuration of the labyrinth. To keep down the size of the volume some of the less important rhinological subjects are omitted. The book has been made available for the military otologist by the insertion of the Government tests for hearing. The present edition contains about 50 more pages than its predecessor, not counting the making good of certain omissions, and the additions in cuts amount to 25 per cent.

THE NORMAL AND PATHOLOGICAL HISTOLOGY OF THE MOUTH. Being the second edition of "The Histology and Patho-Histology of the Teeth and Associated Parts." Revised and enlarged by ARTHUR HOPEWELL SMITH, L.R.C.P., Lond.; M.R.C.S., Eng.; L.D.S., Eng.; Professor of Histology, Pathology and Comparative Odontology, University of Pennsylvania, etc., etc. Volume I, Normal Histology. Volume II, Pathological Histology. Price, $4.50 per volume. Philadelphia: P. Blakiston's Son & Co., 1918.

IT was well to make two separate books of this excellent work instead of enlarging the already cumbrous one volume first edition. While it is somewhat unusual for one writer to cover both normal and pathological histology, this seems permissible in a restricted field like that of the teeth and associated parts. The subject matter of Volume I comprises the histology of the teeth and oral tissues and the histogenesis of the teeth of all dentate animals. The volume is beautifully illustrated with 262 text figures.

THE section on pathological histology in the original volume comprised about 320 pages, while its successor, comprising Volume II, boasts of 469 pages. The number of chapters in the former—eleven—has been expanded to seventeen, the additions comprising as subjects pyorrhea alveolaris, degeneration of the periodontal membrane, diseases of the oral mucosa, odontoceles, dermoid teeth. As indicated by the changed title, the main innovation of the book is the incorporation of the oral tissues. The various changes in these two volumes make of this edition practically a new work, and it is one that can be confidently recommended as an authoritative treatise on oral histology and pathology.

THE A-B-C OF SANITARY HOUSE DRAINAGE. By DR. WM. PAUL GERHARD, Consulting Engineer. Price, 20 cents. Reprinted by courtesy of the Trenton Potteries Co., 1918.

THIS little booklet resembles at first sight a manufacturer's or dealer's trade catalog finely illustrated, but the absence of any proprietary names and devices and of quoted prices and the fact that some of the matter has appeared as magazine literature dispel the impression. The subject is one of exposed plumbing with especial reference to the sanitary requirements of countryside homes.

DENTAL AND ORAL RADIOGRAPHY. A Textbook for Students and Practitioners of Dentistry. By JAMES DAVID MCCOY, D.D.S., Professor of Orthodontia and Radiography, College of Dentistry, University of Southern California. Second edition. St. Louis: C. V. Mosby Co., 1918.

THE first edition of this work appeared in 1916 and was a duodecimo of 157 pages with 71 illustrations. It has been expanded into an octavo of 179 pages with 123 illustrations. The original 9 chapters have been increased to 11, the addenda comprising an introductory chapter and one on the indications for the use of the x-ray in the practice of dentistry.

CHEMICAL PATHOLOGY. Being a discussion of general pathology from the standpoint of the chemical processes involved. By H. GIDEON WELLS, Ph.D., M.D., Professor of Pathology in the University of Chicago and in Rush Medical College, Chicago. Third edition; revised and reset. Price, $4.25 net. Philadelphia and London: W. B. Saunders Co., 1918.

THE third edition of this extremely complete and valuable volume by a most competent authority has been entirely reset and largely rewritten. The very full bibliography has been enlarged and includes articles published in 1917. Hardly a page has escaped alteration and many of the chapters have been entirely changed so as to cover the results of the most recent research. The final section on diabetes has again been revised by Woodyatt. In its enlarged form the volume remains the best and most compact survey in any language of the subject of chemical pathology.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Volume the thirty-fifth. Edited by JOHN F. BINNIE, M.D., Recorder of the Association. Octavo of 616 pages with numerous illustrations. Printed for the Association. Philadelphia: William J. Dornan, 1917.

THIS volume of the Transactions contains the papers read before the Association at the meeting held May 31, to June 1 and 2, 1917. In accordance with the usual arrangement, after the Lists of Officers, former Presidents, Active, Senior, Honorary and Deceased Fellows, there are obituary tributes to six members who died since the previous report was published. These were: Alfred King, Joseph Ford Thompson, Sir Victor Horsley, Emil Ilessel Beckman, Vincenz Czerny, and Paul Monroe Pilcher. The remainder of the book contains the Address of the President, Dr. Samuel J. Mixter, and reprints of the thirty-seven articles which were read at the annual meeting, together with abstracts of the discussion.

WAR WOUNDS OF THE LUNG: NOTES ON THEIR SURGICAL TREATMENT AT THE FRONT. By PIERRE DUVAL. Authorized English translation. Price, $2.25. New York: William Wood & Co., 1918.

THIS translation of the original French comprises chapters on mortality from lung wounds, pathological anatomy of same, fatal hemorrhage, infection, operative treatment, urgent surgery of open thorax, operative technique, and end results. In the Appendix is a study of bacteriology. Under operative technique we find no mention of apparatus for equalizing pressure. Inhalation anesthesia is but little used. The thoracotomy technique of Willy Meyer of New York, with extensive rib resection, is recommended.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Thirtieth Annual Meeting,

Held at Lenox, Mass., May 27, 28, and 29, 1918.

THE PRESIDENT, DR. LINNAEUS EDWIN LAFETRA OF NEW YORK IN THE CHAIR.

President's Address.—The Neglected Period of Childhood.—Dr. L. E. LAFETRA delivered this address, in which he said that the rejection by medical examining boards throughout the country of from 25 to 30 per cent. of men called as recruits, the study of the physical condition of men and women engaged in war industries, and the experience of the warring nations abroad, that under war conditions not only did the birth rate fall and the infant mortality tend to rise, but even older children suffered because of inadequate food and worsened hygienic conditions, had impressed on us the great danger to the nation's children. Already the effect of insufficient food was being felt in this country. In prompt recognition of this situation the Federal Child's Bureau had designated this second year of the war as "The Children's Year," and had inaugurated a campaign for the saving of 100,000 children's lives. This laid upon the members of the American Pediatric Society a special obligation. They should survey the whole field of child welfare work to see what links were weak and give their thought and effort to strengthening the weak places. The period of infancy and that of school age were the only ones that were at all adequately supervised. Prenatal work was now being taken up very extensively everywhere. But when one came to the pre-school age, the period of childhood from two to six years, very little had been done. When we looked among children of the runabout age we found only a small number that looked as well and strong as when they were babies. The impulse as regarded growth was only a little less strong during this period than during the first and second years, and during this period great and important changes were taking place in the brain and nervous system that might make or mar all the rest of the child's existence. It was highly important that the child's food at this time should contain just the right sort of building material for the highly organized protoplasm of these growing nerve cells. The heart also showed important changes at this period of life, and it was likewise true that at this age children were more susceptible to the diseases of childhood than at any other period. The essayist considered somewhat in detail other conditions that might manifest themselves during this period of childhood, such as general malnutrition, hereditary syphilis, tuberculosis, rickets, and backwardness of various sorts, including cretinism and Mongolianism. There were also nervous children, those with adenoid growths, malformed jaws, carious teeth, and enlarged tonsils, that should be cared for during this period. The removal of adenoids and enlarged tonsils was important because their presence encouraged serious complications should the patient later contract measles, diphtheria, influenza, or pneumonia. Acquired heart disease frequently had its inception during the pre-school age, usually following severe tonsilitis, or one of the severe infections. Whooping cough was most prevalent during the pre-school age and was often complicated by gastrointestinal disturbances or bronchopneumonia, and it predisposed to asthmatic bronchitis and to tuberculosis. Systematic vaccination against whooping cough had seemed in some instances to be of great value, and the speaker's experience was in favor of employing this vaccine. The first step necessary toward bridging this gap in our medical supervision was to make a survey of the whole situation. This had already been proposed for New York. A house to house canvass was to be made and the children were to be examined with special reference to the presence of malnutrition, enlarged tonsils, and adenoids, carious teeth, cardiac disease, rickets, and tuberculosis. Appropriate treatment would be advised and the effort would be made to educate the lay public, which was just now in a receptive frame of mind as far as the necessity of periodic examinations went and care of children before they entered school. The importance of protecting children against all sorts of contagious disease, including common colds, would be emphasized. In addition there should be established by the various out-patient hospitals and by the Department of Health, consultations for pre-school children, where the mothers could be taught about proper nutritious food, about clothing, cleanliness of body, hands, and teeth, and about the necessity for fresh air and sufficient hours of sleep. Incidentally such a survey would offer the opportunity to collect data on height and weight of normal children from two to six years of age. Studies of the nutritional requirements of these children when quiet and when at play should also be made. Provision should be made for better ventilation both of sleeping rooms and of rooms where children played. Roof playgrounds, as proposed by Dr. Northrup, would be an admirable solution of this need. When play grounds are furnished children should be compelled to play in the space provided, and not in adjacent streets, and certain blocks should be set aside as play streets where during certain hours no through vehicular traffic should be allowed. Children should not be permitted to play on streets where through traffic was allowed and they should be taught the dangers of the streets. They should be cautioned always to walk and not run across the street, and to look each way, particularly to the left, as they stepped from the sidewalk. The best way of supervising the child during the pre-school period would be to have the children of each district examined at regular intervals, preferably twice a year, at the nearest school in some room set apart for the purpose. Children in need of medical attention either because of undernutrition or special defects should be referred to hospitals or clinics for treatment.

Hæmoptysis Following Exploratory Puncture of the Chest.—Dr. AUGUSTUS CAILLÉ of New York read this paper, in which he reported the case of a child, six weeks old, admitted to the hospital in a markedly cyanotic and practically moribund condition, and giving a history that for the past two weeks she had suffered from symptoms of respiratory embarrassment. To make sure of the presence or absence of pus, an aspirating needle of moderate caliber was pushed into the seventh interspace, into the dull area of the right thorax, about three-quarters of an inch. This procedure was followed by a feeble coughing effort and a brisk hemorrhage from the mouth, and in less than a minute the child was dead. At autopsy the foramen ovale was found patent. Beneath the leaflet of the mitral valve there was an opening into the intraventricular septum about one-eighth of an inch in diameter. The cardiac musculature was about the same thickness on the right as on the left side. There was distinct consolidation of both lungs and marked congestion of the entire lung. There was an extensive hemorrhage into the right pleural cavity. No puncture of a large blood vessel could be made out, and there was no laceration of the lung tissues, as the specimen presented showed. Another fatal sequence to an exploratory puncture came under the writer's notice fifteeen years ago, in which after puncture and withdrawal of the needle a brisk hemorrhage from the mouth took place, and the child was dead within a few minutes. Fatalities from exploratory puncture were exceedingly rare. In the annals of this society now extending over thirty years no such instances were reported. In the writer's own experience of forty years, during which many thousands of exploratory punctures were made, the two cases just reported stood out prominently. The precise conditions under which a simple puncture might be hazardous should be carefully considerd. If a highly engorged lung were punctured a localized hematoma might result, and if, in addition, the clotting time of the blood were prolonged, as it frequently was in cachectic individuals with an acquired hemorrhagic diathesis, a free remorrhage into the pleural cavity or trachea might take place. The introduction of an exploratory needle into a thorax containing a highly congested lung was attended with some degree of risk when cyanosis and other characteristic signs pointed to cardiac or circulatory failure.

Breath Holding in Children.—Dr. ISAAC ABT of Chi-

cago presented this paper, in which he stated that breath holding might lead one to believe at first glance that the attacks were associated with laryngismus stridulus, but closer investigations would show that such assumptions were erroneous. The breath holding attacks manifested no true laryngeal spasm. The breath was restive or stopped suddenly in the midst of a crying attack, but there was no inspiratory spasm. The child usually worked himself into a rage, cried for a time, and then suddenly stopped, finding it impossible for a time to make any further sound. The child threw himself about or became cyanotic or pale; then the body became rigid and the eyes turned back or became set. For a moment it seemed that the child was asphyxiated. The attack usually lasted a few seconds and then disappeared. It might, however, continue for several minutes, and was sometimes followed by convulsions. Breath holding attacks were differentiated from minor epilepsy in that they followed immediately upon severe crying, excitement, or anger, while the epileptic attacks occurred suddenly in the midst of quiet play or even during sleep. Biting of the tongue which occurred in epilepsy did not occur in breath holding. Involuntary evacuation of the bladder or rectum might occur in both breath holding and epilepsy, and a long sleep might follow in either condition. The attacks of breath holding occurred in neuropathic children and were brought on by fear, anger, fright or some other psychic trauma. As a rule children subject to such seizures were irritable and ill tempered. The condition was frequently aggravated by neuropathic parents who feared the occurrence of these attacks and humored the child in every way. Children who fell ill with acute infectous diseases, or who by reason of accident or injury required surgical treatment, might be seized with a severe breath holding attack accompanied by general convulsions as a result of fright, and under such circumstances the attack might be so severe as to end fatally. Treatment should be directed toward the general management of the child. Stimulation should be avoided and the child should be ignored as much as possible by parents and friends. When the attacks occurred there should be no hysterical manifestations evinced by the mother or nurse. Cold water dashed into the face had been recommended as a direct remedy. Finally the patient should be shown in no uncertain manner that any repetition of the attacks would meet with harsh if not painful measures.

Dr. Rowland G. Freeman of New York cited a case of breath holding coming under his observation. The parents of the child were healthy, robust people. The attacks were sometimes prolonged until the child became unconscious. Two years ago the child had a cold and got one of these attacks, during which it became unconscious and died without recovering consciousness.

Dr. Percival J. Eaton of Pittsburgh described his experience with three boys belonging to one family who were subject to these attacks. There was a fourth boy in the family who did not have these rage spasms. He found that by forcing the mouth open and drawing the tongue out and then pulling the cheeks in some reflex was excited which relieved the spasm of the glottis. There was nothing in the psychology of these children to account for the attacks, and their parents were not neurasthenic.

Dr. Henry Heiman of New York stated that some of these cases were cases of simple breath holding, but there were other cases, borderline cases, which presented a condition very much like spasmophilia or Erb's phenomenon. Dr. Abt had described the correct treatment for breath holding.

Dr. Abt, in closing, said that none of these cases occurred until about the second year, whereas spasmophilia manifested itself earlier; he therefore felt confident that these were not cases of spasmophilia. Of course one could have spasmophilia without the classical symptoms. These children described in the paper were first of all ill-tempered; would have short crying spells, and would then develop the attack. There was not sufficient ground for saying that they were cases of spasmophilia.

Dr. L. E. LaFetra said that we all met these cases and the important point was that we had assumed that we could assure the family that these children would not die as a result of their breath holding. We had now heard of an instance in which a child did die as the result of such an attack. However, he felt that they were pretty safe in making the statement that these children were not going to die as a result of these attacks; they were ill-tempered, lacked self control, and had a nervous inheritance. They were comparable to the children who could vomit at will. Neglect and punishment was the proper method of treatment.

Death from Cardiac Failure in Children, Unexplained by Post Mortem Examination.—Dr. John Howland of Baltimore read this paper, in which he said that a certain form of cardiac disturbance in adult patients had been recognized, which resulted in death with marked evidence of circulatory failure, but with no other changes to be made out other than great cardiac hypertrophy and more or less dilatation. The hypertrophy was the striking feature. The musculature was intact. The writer had not been able to find any thorough discussion of this condition in adult medicine, and none in pediatric literature. His attention was first attracted to the subject by a patient who came under his care when three months old, suffering from extreme malnutrition, largely due to the fact that she regurgitated her food. She was finally discharged in a fair condition at the age of eleven months. She continued to gain until 15½ months of age, when she began to have marked respiratory distress with an expiratory grunt. Her temperature was normal but respirations and heart action were rapid. It was made out by physical examination and confirmed by *x*-ray that her heart was greatly increased in size. She eventually died from circulatory failure without edema, one month after the onset of her symptoms. At post mortem nothing was found beyond a very much enlarged heart, which weighed 100 grams, the average weight of the heart for this age being 46 grams. All the other organs were normal. Dr. Howland reported three other somewhat similar cases. He said that an explanation for the cardiac hypertrophy had been sought elsewhere in the body, but none of the conditions with which cardiac hypertrophy occurred was present in any of these cases. The myocardium in all of the cases reported by the speaker was normal. There might have been some disturbance on the part of the nervous mechanism of the heart akin to that present in Graves' disease. There was reason for believing that as the result of some nervous or muscular disturbance there was incoordinate action of the heart, and this for the reason that loud murmurs might be heard, not as the result of valvular disease as shown by post mortem examination and apparently not due to extensive dilatation of the valvular orifices. The writer believed that in its milder grades this cardiac condition was more frequent than was suspected, for he said he could distinctly remember patients from two to four years of age with enlarged hearts and with the symptoms of acquired cardiac disease, as opposed to congenital disease, in whom it was impossible to demonstrate any etiological cause.

Dr. Charles Hunter Dunn of Boston recorded a case similar to those described by Dr. Howland. This baby suffered from marked cyanosis and cardiac insufficiency and a diagnosis of double pleurisy or hydrothorax was made. The *x*-ray showed that this was a cardiac case. It was thought to be one of pericarditis with effusion. The outline of the heart extended to the lower portion of the chest wall on both sides, being much larger in proportion to the size of the child than those shown in Dr. Howland's plates. As in Dr. Howland's cases, the heart muscle was normal and there was nothing to explain the hypertrophy.

Infantilism, with Reports of Two Cases Illustrating the Brissaud and Frölich Types Respectively.—Dr. J. P. Crozer Griffith of Philadelphia presented this paper. He expressed the opinion that the term infantilism should be applied not only to adolescents or adults who possessed in some degree the bodily and often psychic characteristics of infancy, but to children of any age in whom there was a persistence of characters, especially sexual, which belonged to a period of life decided earlier than the actual age of the patient. A sharp distinction should be drawn between infantilism and nanism. The first case reported was that of a child, seven years of age, Italian, who entered the

Children's Ward of the Hospital of the University of Pennsylvania on January 12, 1912. When one and one-half years of age she had an attack of whooping cough and since that time she had not grown any physically, although the parents thought she was normal mentally. She frequently cried and complained of pain. Physical examination showed short extremities in comparison to the size of the thorax, and the legs were slightly bowed. The child walked with a wobbling gait. She weighed 20 pounds while the normal weight for her age was 49 pounds. Her height was 29 inches, the normal for her age being 45 inches. The chest was short and full and there were slight subcutaneous fatty deposits in the supraspinous fossa. The abdomen was much distended resulting in a distinct costal flare and producing a compensatory lordosis of the spine. During the patient's five months' stay in the hospital she gained one pound and showed a slight increase in measurements, but no very material change. During her early stay in the hospital thyroid extract was given. On May 3 the thyroid extract was discontinued and pituitary given until May 27, in doses of one grain, three times daily. The suggestive symptoms of infantilism of the Brissaud type were moderate harshness of the skin, bowing of the legs, prominent abdomen and the moderate deposits of fat over the scapulæ, all of which pointed to hyperthyroidism, not of a degree to produce cretinism, but sufficient to make the cretinoid. The *x*-ray findings were negative, there being nothing in them to suggest achondroplasia, nor were there any other symptoms of this affection. The second case occurred in a male, 11 years of age, who was admitted to the hospital for excessive obesity. The tendency to undue deposit of fat had been noticed by the parents since the child was 11 months of age. This had been gradually progressive and did not seem to be influenced by diet. The boy was five feet in height, the normal for his age being four feet; he weighed 251 pounds, the normal for his age being 70 pounds. The boy walked with a distinct limp, his abdomen was very fat, and his penis was buried in fat and was very small for the rest of his development. The *x*-ray examination of the head showed the sella turcica distinctly smaller than normal, indicating a small pituitary body. The boy had a marked sugar tolerance; after the administration of pituitary extract there was a decrease in the sugar tolerance. After a little less than four months' stay in the hospital the boy was taken home, having lost only 17 pounds. This was an excellent instance of pituitarism of the Frölich type, except in certain particulars. The infantile character of the sexual organs, the great obesity and its distribution, and the tolerance to carbohydrates were positive indications. On the other hand the subjects of Frölich's syndrome often exhibited a retarded skeletal development, while this patient possessed a decided overgrowth. This might depend on excessive action of the anterior lobe combined with insufficiency of the posterior lobe. The excessive action of the anterior lobe was the condition which, if developed in later life, would result in acromegaly, but appearing earlier, as Brissaud suggested, produced gigantism.

Dr. CHARLES HERRMAN of New York deplored the loose way in which the term infantilism was employed. The term infantilism had been used for all forms of dwarfism. He thought it might be better to use the term dwarfism for retarded growth and infantilism to designate an absence of secondary sex characteristics. It was a good plan to examine the metacarpal bones. Some of these patients showed marked improvement under thyroid treatment. The tendency was to give pluriglandular extracts.

Dr. GRIFFITH said that the bones were examined and nothing abnormal found in the first case. In the second case only the bones of the skull were examined. He thought the term infantilism was pretty thoroughly defined and that it had been accepted as designating a slowness of development and not of growth.

Head Shaking with Nystagmus in Infants. A Study of Sixty-four Cases.—Dr. CHARLES HERRMAN of New York presented this communication. He stated that this condition seemed to be more common in some countries than in others and was certainly more common in large cities as was shown by a study of the statistics of both European cities and of New York and Philadelphia. The figures in New York City indicated that the condition was met with in about one in every seven hundred infants coming under treatment. The number of cases varied markedly in different years and was more common among negro than among white children in New York. This was probably due to the poorer hygienic conditions and the greater prevalence of rickets among colored children. Females were slightly more frequently affected than males, there being 29 males and 35 females in the series reported. The disease showed a distinctly season incidence, nearly 70 per cent. of the cases occurring in December, January, and February, and apparently bore a direct relation to the number of hours of sunlight. It was most common between the ages of four and twelve months, 75 per cent. of all cases occurring at that time. The writer's youngest patient was four weeks, and the oldest four years of age. In very few of the cases was there a distinct neuropathic history. The character of the feeding seemed to have no direct relation to the disease, though, as might be expected, the rachitic manifestations when present were more marked in the artificially fed infant, so that, to a certain extent, such infants were somewhat more predisposed to headshaking. Previous illness, by lowering the vitality, was apparently an etiological factor in those infants that were already predisposed. The author had not been able to convince himself that teething played an important rôle in the etiology of the disease. Trauma might be an exciting cause in a predisposed child. Hygienic conditions, social position and the location of the rooms played an important part in the etiology; head shaking in large cities had been found to be more common among those who lived in the poorer tenements and among families living in the basement and on the first floor. In 55 of the cases in this series the character of the rooms could be accurately ascertained, and in 40 of these the infant was more or less in the dark. But with reference to darkness as an etiological factor we must also assume an individual predisposition. The same predisposition had been noted in miner's nystagmus. During the past 11 years the writer had studied the same class of people at the Lebanon Hospital Out-patient Department in the Borough of the Bronx as he saw from 1899 to 1901 at the Good Samaritan Dispensary, on the Lower East Side of New York, and he found that the disease was more common in the latter section, due principally, in his opinion, to the fact that in the Bronx the majority of families lived in better lighted and ventilated rooms. Head shaking was apparently about twice as frequent among rachitic children as among others. Cases of nystagmus were rarely associated with laryngismus stridulus, facial irritability, tetany, or convulsions. The pathogenesis of the condition was still somewhat of a puzzle. The writer, in considering the pathology of these cases, accepted as a fact the obvious relation of the head and eye movements and believed that in the progress of the medullary development of the nerve supply, which was going on at great rapidity at this age, was interfered with by disturbance of nerve nutrition. In this series of cases the movements of the head were primarily horizontal in 44, vertical in 12, rotary in four, and horizontal or vertical at different times in four. In this series of cases the movements of the extremities described by Still, Thomson, and others, were not observed. In 35 of the cases the nystagmus was bilateral, in 23 unilateral. The movements of the eyes in these cases were very much more rapid than the movements of the head, about 200 to 300 per minute. The prognosis was good. The treatment should aim to improve the hygienic conditions and provide light. Any source of peripheral irritation should be removed, the diet regulated, and digestive disturbances corrected. Codliver oil and codliver oil and phosphorus should be administered to those infants presenting rachitic symptoms.

Dr. AUGUSTUS CAILLÉ of New York recalled that twenty-five years ago he had read a paper before this society on this subject in which he had demonstrated that if the child's eyes were tied up the head nodding would stop.

Dr. HERRMAN said he wished to state that he had

given Dr. Caillé credit for the point he had just made. He had found that in every instance in which the child's eyes were tied up the head had stopped nodding.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held October 4, 1918.

DR. SETH M. MILLIKEN IN THE CHAIR.

Compound Fracture of the Tibia, Fibula, and Femur in a Young Child; Nail Fixation.—Dr. LUCIUS A. WING presented this patient, a little boy six years of age, who was admitted to St. Mary's Hospital for Children on July 18, 1918. He had been run over and in addition to minor injuries had sustained compound fractures of both bones of the leg and of the femur, three inches above the knee. The skin of the leg was badly lacerated and also the gastrocnemius muscle, and the child had lost much blood. Owing to the extensive lacerations the application of splints did not seem feasible. Dr. Farr suggested the Steinmann nail and repair was effected by the nail placed through the os calcis. The extensive lacerations prevented the use of the traction apparatus and hence the leg was lightly suspended. The lacerations were treated with Dakin's solution. The injuries were not dressed until eighteen hours after they had been inflicted. The leg was retained in suspension from July 18 to August 19. A spica was applied in such a way as to leave the leg from the knee to the ankle exposed so that it could be dressed. The *x*-ray showed that there was some actual lengthening of the limb as compared with the opposite side. *X*-ray pictures were taken ten days after the suspension was applied and last week were exhibited for comparison. The boy had made an excellent recovery and, though he was not yet walking, he would walk in a short time.

Dr. FENTON B. TURCK said he was interested in Dr. Wing's case because he had had a number of similar cases in which shock following injury was as severe as in this child. This boy had been run over and eighteen hours afterward was still in such severe shock that it was necessary to give him subcutaneous injections of salt solution and to employ extreme care in the administration of an anesthetic. Dr. Wing was very fortunate in having had such a successful outcome in this instance for where there was maceration and destruction of tissues there occurred at once autolysis, a rapid digestion of tissue substance, which on absorption of these products produced the phenomena of shock, with venous stasis in the splanchnic area, and this led to a higher viscosity of the blood. Hence thinning the blood in such cases was very useful. He had had a case with a pulse of 160 to 170 and put in 30 c.c. of a shock antitoxin serum made by injecting a horse with autolyzed human tissue, and this caused an immediate reaction and relief from the shock. The following day a second injection was given and the patient made a rapid recovery. Several other cases of a similar nature treated in this way had immediately responded to the serum, and he believed this was one of the most effective agents in rendering the blood less viscid and preventing autolysis. In a second case of gangrene, due to the *Bacillus aerogenes capsulatus*, Dr. Turck stated that he had injected a mixture of human tissue on which was cultured this organism and the colon bacillus into a horse, and this gave a different serum than the former bacillus alone, producing an antitoxin of higher potency and more readily preventing autolysis and hence preventing the gas bacillus from growing in the autolyzed tissues. He had not only used this antitoxin against gas bacilli but (by adding streptococcus cultures to the antigen) also had found it effective in streptococcic infections. He had been working on this problem for several years and thought his results would prove a most useful and valuable addition to surgical work.

Amputation of Hand Except Thumb After Compound Fracture of Metacarpals, with Gas Bacillus Infection.—Dr. WESLEY GROVE VINCENT presented this case. The patient was an automobile mechanic, 25 years of age, who was admitted to the Harlem Hospital on June 23, 1918, with the history that while repairing an automobile the screw-jack under the car slipped, catching his left hand and cutting through the upper part of the hand. The skin and tendons were cut through and the metacarpals fractured, the thumb alone escaping injury. Upon admission to the hospital the hand was very dirty and greasy and some attempt at cleansing the injured area by iodine sterilization was made by one of the house staff and a wet dressing was applied. The temperature on admission was 98° but later dropped to 97°, then gradually rose to normal and on the following day reached a degree or two above that point. It was supposed that this would be a suitable case for tendon suture, but when the dressings were removed in the operating room it was found that the blood supply to the dorsum of the hand had been almost completely cut off and that the parts below the line of compound fracture were fast becoming gangrenous and were infected with the *Bacillus aerogenes capsulatus*, as shown by the crepitation under the skin and the air bubbles at the cut surfaces, and later by bacteriological study. Consequently a palmar flap reaching nearly to the digitopalmar fold was cut and dissected up, hugging the anterior surface of the metacarpals, to the points of fracture; a few snips of the scissors then completed the amputation. With the scissors and rongeurs all frankly gangrenous and contused tissues and stumps were removed until free oozing of blood was encountered. There did not appear to be any gas bacillus infection of the proximal tissues (above the line of traumatic incision) when the field had been cleared of damaged tissues, so operation at a higher level was not considered necessary. The field was flooded several times with peroxide, the flap was left unsutured, a large wet dressing was applied, and instructions were given that the hand and arm were to be kept immersed in 1-3000 permanganate solution. The temperature shot up to 104° F. that evening, dropped to 101° the following day, and then ranged between 99.5° and 101° for the following four days; it then gradually declined to normal. By July 9 the wound had cleaned up sufficiently to allow revision of the stump and skin graft. A few necrosed spots in the skin edges were trimmed away and all unhealthy areas were excised. The entire field was then swabbed with 7 per cent. tincture of iodine, followed by alcohol and saline solution. The skin edges were freshened and the palmar flap was brought up as far as possible and tacked by two silk-worm sutures. Thiersch grafts were then applied to the remaining raw surface. These were covered with sterile rubber tissue which had been folded twice and cut with straight scissors nearly the full width of the folded piece at intervals of about one-quarter inch, so that secretions were easily absorbed by the overlying gauze, but the gauze did not come in contact with the grafts themselves at any point. Practically all the grafts took and the patient was discharged from the hospital on July 22, at which time epithelialization was practically complete.

Dr. MILLIKEN asked Dr. Vincent if a culture had been made in his case and the gas bacillus found.

Dr. VINCENT said that a culture had been made and the gas bacillus was identified. He said he wished to call attention to one point in reference to the application of the rubber tissue. He took a piece of rubber tissue, folded it upon itself two or more times, then took straight scissors and cut the rubber tissue at intervals perpendicular to the folded edge and nearly as far as the other edge, and then placed it over the graft, so that there was no point at which the gauze touched the graft and yet the openings in the rubber tissue permitted of drainage and the gauze over the rubber tissue absorbed the secretions. This point was valuable in the treatment of most ulcers, especially leg ulcers. If they were dressed in this way one did not take off part of the granulations when one removed the dressing, and the ulcer would then heal much sooner.

Echinococcus Cyst of the Liver.—Dr. JOHN COLIN VAUGHAN presented this patient, a Greek woman 35 years of age, admitted to Bellevue Hospital on November 5, 1917. She gave a history of having had a still birth one week before admission, following which she had developed a pain in the right side and shortness of breath. She came to this country about a year ago and shortly afterward developed a pain in the right

side and a cough. Her health previous to this time had always been good. A physician had introduced a needle and withdrawn a large quantity of watery fluid. Physical examination at the time of admission to the hospital showed the woman poorly nourished, dyspneic, restless, anxious, and appearing ill. Examination of the lungs showed harsh breathing on the left side, the left lung being otherwise negative. The upper right lobe of the lung was clear. Below a line extending from the inferior angle of the scapula through the nipple in front the chest was flat with the absence of fremitus, breath, and voice sounds. Over this area there was tenderness on pressure. Examination of the heart showed the apex in the fifth space, the sounds loud, clear, and booming, and the muscular quality fair. The abdomen showed an oval swelling in the right upper quadrant. The liver was four cm. below the costal margin, smooth and tender. The spleen was not felt. The uterus was palpated above the symphysis and was tender, soft, and boggy. There was a moderate purulent vaginal discharge. The lips were dry and parched, the tongue dry and coated. The temperature was 103° F., respirations 28, and pulse 130. The diagnosis was abscess of the liver, sapremia, and pleurisy with effusion; on November 7 a needle was inserted into the chest under local anesthesia in the fifth interspace and 39 c.c. of clear watery fluid was obtained, apparently under pressure. Examination of this fluid showed red cells and a few white cells. The blood culture was negative. The fluid showed no reduction of Fehling's solution and no cholesterin. The impression was that the patient had an echinococcus cyst of the liver or a subphrenic abscess. On December 6 a needle was inserted in the sixth interspace and three and one-half ounces of light greenish fluid was obtained. Hooklets were not present, nor was there any bile present. No ova were found in the stools. The patient was *x*-rayed and it was found that she had a high diaphragm on the left side. She was transferred to the medical side, where a little later hooklets were found and the fluid was seen to reduce Fehling's solution. The fluid contained no albumin and very few cells. The patient was operated upon on December 13. A part of the ninth rib was removed and the liver sutured to the abdominal wall. The liver was found smooth and tense and the wall very tough so that it was sutured with difficulty. Several quarts of cysts and daughter cysts were taken out. The cavity was thoroughly cleansed and flushed out several times. There seemed to be very little liver substance left. A pear-shaped body was found which was thought to be the gall-bladder and from which bile was obtained. Large drains were placed and the patient returned to the ward. A great deal of serous fluid and later bile was drained through the wound. The stools became light in color though they were never clay-colored. Some bile continued to be discharged until January 23 when it ceased and only a small amount of light purulent fluid drained away. No cysts were discharged after the operation. The pathological department reported that the specific gravity of the fluid was 1,096, albumin 1.53 per cent., and sugar 53 milligrams per 100 c.c., running rather high for an echinococcus cyst. The microscopical examination of the cyst wall showed a laminated appearance. It was apparently made up of granulation tissue and what appeared to be granulation tissue. After leaving the hospital the patient continued to drain until April 2, when the wound was allowed to heal. There was at the present time no enlargement of the liver and physical examination was negative.

In reply to the question as to whether he had found an eosinophilia in his case of echinococcus cyst of the liver, Dr. Vaughan said that blood counts were made but they were somewhat clouded because of the sapremia, but the eosinophile count was never very large, being below one per cent. It was said that echinococcus cysts were quite frequent in countries where the people were closely associated with dogs. The speaker had spent two years in the Arctic region where the men were constantly associated with dogs but no instance of echinococcus infection had come under his observation. He had during this experience found every kind of parasite—tapeworms, flukes, etc.—but never an echinococcus infection, so he was inclined to think that an infection of this kind derived from a dog was more or less accidental.

Dr. MILLIKEN recalled a case of echinococcus cyst of the pleura coming under his observation. The patient came into the hospital in June, 1917, and thinking that he had an empyema, the house surgeon aspirated him but got only a dry tap. Later Mr. Milliken aspirated him and said that he too obtained only a dry tap. The man's condition was not sufficiently serious to warrant an operation so he was transferred to the medical side. Dr. Henry Thatcher aspirated and obtained the characteristic fluid containing hooklets. He was then operated upon, through an intercostal incision, using the Lilienthal retractors. An echinococcus cyst was found about the size of a polo ball and a similar sized sacculated empyema next it. After the removal of these an enormous cavity was left. The lung did not expand at the time of the operation, but came down later. The cavity was drained for five weeks and then gradually healed, the patient making a good recovery.

Dr. WILLY MEYER called attention to several interesting points in connection with this case. The first point was that aspiration was always risky, though in some cases it could not be avoided. The second point was the way of attack; he thought the only proper way was to go through the pleural cavity. In doing this it was a great help to put a pillow under the patient's back so as to produce a convexity of the thorax and upper abdomen. The third point of interest in this case was the continuous discharge of bile which persisted for quite a time. It was this feature which prompted him to inquire as to the character of the cyst wall. Sometimes it was possible to peel out small cysts just as one peeled out the gallbladder from its bed, but this could not always be done with larger cysts. Dr. Meyer recalled a case of echinococcus cyst coming under his observation some years ago which was only drained and treated with antiseptics for two weeks and all seemed to be going well, when there was a rise in temperature and a few days later the cyst wall came into the wound and the entire cyst was then removed. This illustrated very nicely how nature sometimes came to the rescue. Dr. Meyer asked whether the pathological report was on the wall of the whole cyst or of one of the smaller cysts.

Dr. VAUGHAN said that the report was on the parenchymatous cyst wall. The inner wall was granular in type, but it was not granulating tissue. It was from this layer that the heads of the daughter cysts grew. It was well known that if a cyst ruptured there was rapid absorption of the toxins present in the fluid and that these toxins rapidly caused death, and the same thing had happened from aspirating through a large cyst. If one was suspicious that he was dealing with an echinococcus cyst he should use a small needle in aspirating. The operation of choice was a complete clearing out of the cyst the minute it was opened, for if a lacerated cyst were left in, absorption would take place and one would get a case of toxemia.

A Case for Diagnosis.—Dr. HENRY W. FRAUENTHAL presented a boy of Hebrew parentage, 3 years of age, who had a bilateral affection of the tips of the fingers in which the temperature of the tips of the fingers was 10 to 15 degrees lower than that of the palm of the hands. A similar condition was never seen in a child of that age, the youngest case of obliterating arteritis having been seen in a boy of 17 years. It was thought that this might possibly be an early type of Raynaud's disease, in which the finger tips had that bluish-black hue.

Dr. ALFRED F. HESS said that these cases were reported from time to time but no absolute diagnosis was made as he remembered. The first thing to think of was a lesion of the spinal cord, probably some atrophic condition. There had not been a careful enough examination of this child made to venture an opinion as to the diagnosis. If this child were placed in a hospital and tests were made as to sensation, motor power and reflexes one might then say whether or not the spinal cord was involved. Another condition to be thought of was one which occurred in young babies in which the hands, feet and nose were affected and the process went on until death occurred. In some such cases hemorrhage of the adrenals had been found. That would be a condition very difficult to diagnose; the one feature on

which to base a diagnosis in such a case would be low blood pressure. The blood pressure in babies is about 100 or 90 mm.; if it is below that one should consider the possibility of a lesion of the adrenals.

Dr. Leo Buerger said that though he had only a passing glance at the child presented by Dr. Frauenthal he felt certain that thromboangiitis could be ruled out on the absence of pulsating vessels. In thromboangiitis of the upper extremities there was always absence of pulsation of the radial artery and sometimes of the ulnar artery. If the condition were thromboangiitis one would expect to find the lower extremities involved and Dr. Frauenthal stated that there was no involvement of the lower extremities. Thromboangiitis is associated with obliteration of blood vessels. If we began to consider other vasomotor conditions in which there was no obliteration of the blood vessels as belonging to this class, the result would be such a confusion of the whole question of vasomotor vs. organic diseases of the blood vessels that differential diagnosis would be impossible.

The Etiology of Thromboangiitis Obliterans.—Dr. Willy Meyer read this paper, which was based on extensive clinical observations and a variety of laboratory examinations of patients suffering from so-called thromboangiitis obliterans. The chemical examination of the blood of these patients had shown that (1) There was no retention of waste nitrogenous constituents. (2) There was no marked decrease in the alkaline reserve of the blood, as demonstrated by the carbon dioxid combining power of the blood plasma (method of Van Slyke). (3) In all the cases thus far studied, the ingestion of 100 gm. of glucose, after a brief fasting period, had produced hyperglycemia. This observation shifted the whole question of the etiology of the disease to new ground, and the old designations appear no longer appropriate. For the present Dr. Meyer proposed naming the disease glycophilia. The similarity of the name to hemophilia was intended to point to sex limitation and other obscure features of the disease. (See Medical Record, June 29, p. 1142.)

Dr. Leo Buerger said he thought we should welcome all studies which had for their purpose the investigation of the causation of thromboangiitis and Dr. Meyer was to be congratulated upon having investigated this subject from a new viewpoint. But just how much light he had succeeded in throwing on it by his particular investigation we could not say at the present time. Dr. Buerger doubted those conclusions according to which thromboangiitis was a disease of the blood rather than of the blood vessels. A distinction should be made between thromboangiitis and the gangrene of these other diseases in which the blood vessels remained patent. Thromboangiitis was a disease in which the blood vessels were extensively closed and in which this closure of the vessels could not be attributed to traumatic or thermic causes. It was a specific disease accompanied by specific changes in the blood vessels. The fallacy in Dr. Meyer's conclusions was that he reasoned that because, after certain therapeutic measures, certain vessels had become *quasi* patent, he had actively restored their lumina and that the evidence afforded by palpation was better than that of the microscope. Personally, Dr. Buerger said he could never convince himself—though he had many cases under treatment with Ringer's solution—that pulsation was ever restored in a vessel occluded by thromboangiitis. His experience led him to believe that pulsation was never restored, if one meant thereby a restoration of the lumen of the vessel. What might happen was that there might be two portions of a vessel occluded with the intervening portion unaffected by the thromboangiitic process. Through the patent portion of the vessel, usually the dorsalis pedis and lower anterior tibial arteries, a very small amount of blood, insufficient to give a pulse ordinarily, seeped through. After raising the blood pressure by increased inbibation of fluids and subcutaneous injections, it was conceivable that this blood supply of the patent portion of the vessels could be so much enhanced by way of the collaterals as to produce the sensation of pulsation, previously absent. Thromboangiitis had two stages, an acute or inflammatory stage and a chronic or healed stage. The acute stage we often knew nothing about; it was the chronic stage that gave the trouble. In the acute stage the patient might have nodules along the superficial veins and an acute phlebitis, and if we cut out such a vessel and examined it we found it acutely inflamed, difficult of dissection, the wall infiltrated, and many polymorphonuclear leucocytes present. We would find miliary nodules containing pus cells and giant cells, looking very much like the lesions of tuberculosis. There would be also a secondary red clot which was organized and contained the usual elements found in blood clots. The former Dr. Buerger regarded as the *specific lesion of thromboangiitis* and the latter was secondary to it. Dr. Meyer had called attention to glycophilia as an etiological factor; if this were a factor on the causation of thromboangiitis, why did not diabetics give the clinical picture of thromboangiitis or why did we never find the specific pathological changes in the thrombosed vessels of diabetics? In diabetics who had vascular occlusion we found the typical bland thrombi seen in other thrombotic processes. The specific thrombotic lesions of thromboangiitis were characteristic of this disease and were dependent upon a specific organism or toxin.

Dr. Fenton B. Turck said he had recently finished some experiments on this question, and some of the protocols were exceedingly illuminating. If one took any of the tissue of a cat and allowed it to autolyze for twelve hours, then centrifuged it and put 4 c.c. in salt solution drop by drop, and then injected it into an artery, clotting would be found at the end of the arteries commencing in the capillaries. Dr. Turck said he had specimens of thrombosed vessels showing large sections of an artery involved, the thrombosis beginning at the point where the artery stopped and the capillaries began, which he had produced by introducing the autolysins in the main vessels. Doctors were agreed that there was an increased viscosity of the blood, but this was due to the effect of the tissue autolysis, the products of which entered the circulation, and reaching the periphery, produced thrombosis. Experimentally this phenomenon could be produced in animals, and it occurred in human tissues.

Dr. Henry W. Frauenthal said that there were two ways of considering a patient: one from the standpoint of scientific investigation, and the other from the standpoint of relieving the symptoms for which you were consulted, that was, relieving the pain. As to thrombo arteritis obliterans: In a paper read before the 16th International Congress, Surgical Section, at Budapest, September, 1909, Vol. 2, page 906, he reported on twenty-two cases of that disease that were treated with white light from a 500-candlepower incandescent lamp. The patient shown here tonight was one of those reported. When first being treated he was losing his little toe nail, his toe was black and promised to develop gangrene. The little toe improved and a new nail grew. The patient had, however, lost part of the big toe on his right foot. He was under treatment for three years, and had received no treatment for the past eight years showing the efficiency of the white light treatment. This same treatment had been applied in hundreds of cases at the Hospital for Deformities and Joint Diseases. The brother of the above-mentioned patient lost one leg by amputation at the age of 19, and at the age of 21 had the other leg amputated. Dr. Frauenthal said they felt that they saved from 60 to 65 per cent. of their obliterating patients from amputation by the use of white light. While treating them with the light and heat of an electric bath, the pain was relieved. Heat when applied by the Tournier baker, even tried at 450 degrees, gave no relief from pain. The use of morphine and other anodynes was contraindicated in thromboangiitis obliterans because they tended to slow down the circulation and in this way increased pain. Another case was then mentioned by Dr. Frauenthal, that of Dr. M., who had one leg amputated at the middle third of the tibia, and whom he saw the day before he was to have the other leg amputated at the Presbyterian Hospital. This happened four years ago, at which time this patient was taking three grains of morphine to relieve the pain. By the use of white light and no other form of treatment his leg was saved; he had remained well since that time and had discontinued the use of morphine. From time to time he had combined the white light treatment at

the hospital with other methods, such as organic extracts, Ringer's solution, etc. They felt that they owed their results mainly to the properties of the white light. In a number of cases he had suggested that when the opportunity afforded the patients should expose their feet to sunlight. Regarding Dr. Meyer's statement that he had found only Hebrews afflicted with this disease, the speaker said that he had seen several cases in a number of other nationalities.

Dr. Isaac Levin said the seeming disagreement between Dr. Meyer and Dr. Buerger was the usual disagreement between the anatomist and the physiologist or clinician. Some ten years ago he had the pleasure of listening to Dr. Buerger's presentation of this subject, and while he admired his work and original conclusions, he would have to state that in their study they had failed to find the specific nodule and the consistent presence of the condition described by Dr. Buerger. Dr. Buerger was right in thinking that the condition looked different from that shown in other specimens of gangrene, nevertheless, physiologically and clinically speaking, he thought Dr. Meyer was thoroughly correct in saying that there was some sort of connection between diabetes and the condition known as endarteris obliterans, and there was some relation between andarteris obliterans and Raynaud's disease. If a physiological contraction of the blood vessels happened frequently enough and lasted long enough, one might find the same anatomical condition as in endarteritis. Raynaud's disease, endarteritis obliterans, diabetes with gangrene, and diabetes without gangrene shaded into each other.

Dr. Harry Finkelstein said that after listening to Dr. Buerger tell of the inflammatory condition that existed in the acute stage of endarteris obliterans one could understand why heat was unbearable and increased the pain in such cases, and that there was nothing worse for patients suffering with thromboangiitis than baking. His experience with heat was confirmatory of Dr. Buerger's conception of the condition present in thromboangiitis. He thought that when it came to the treatment of this condition it was not wise to advocate any one method.

Dr. Meyer, in closing, said he could not and would not discuss the correctness of the pathological examination, but he would like to emphasie Dr. Levin's remark in reference to the difference of opinion that resulted from looking at the question from the pathological and the clinical standpoints. It was generally conceded that only the male sex was affected by thromboangiitis, and the instance mentioned in the discussion in which a woman developed the disease after the removal of the sex organs confirmed the theory that there was something in the female which prevented the disease or something wrong with the testicular absorption that bore an etiological relation to the condition. Dr. Meyer presented evidence to show that a return of pulsation had been observed in cases that presented the typical symptoms of thromboangiitis, and asked why, if the condition were due to a change in the blood vessels, one found an altered blood picture, as in certain of the cases considered in his paper in which the red blood cells numbered as high as 7,000,000, and there was also an increase in the blood platelets. In concluding, Dr. Meyer said the subject offered a wide field for investigation, more than could be covered by any one man, and that a philanthropist could do no greater service for humanity than to establish a fund for the study of this disease which was the cause of intense suffering to a considerable number of people.

Stated Meeting, Held November 1, 1918.

Dr. Seward Erdman in the Chair.

Rectocolonic Affections and Operations. Including (a) Colectomy for Multiple Adenomata (Polyposis), (b) Resection of the Ileocecal Angle for Neoplastic Tuberculosis, (c) Vaginal Excision of the Rectum for Carcinoma, and (d) the Technique of Anorectal Operations Performed Under Local Anesthesia.—Dr. Samuel Goodwin Gant made this presentation, which was illustrated by motion pictures. He said that surgeons were not sufficiently familiar with rectocolonic tumors, which were encountered more often in men than in women and more often in persons between twenty and forty years of age than was generally supposed. Nearly all varieties of tumors, fibroma, adenoma, myoma, sarcoma, and carcinoma, were encountered in the colon and rectum. *Colectomy.*—The first operation illustrated was colectomy for multiple adenomata or polyposis. The colon when opened showed numerous innocent and occasional growths that had degenerated into malignancy. *Resection of the Iliocecal Angle.*—This operation consisted in extirpating a large tuberculous tumor involving the cecum and lower ileum. When opened in front of the camera the tumor exhibited the characteristic appearance of hyperplastic tuberculosis occasionally encountered in this region, and which was usually mistaken for inoperable carcinoma. *Vaginal Excision of the Rectum.*—The next motion picture demonstrated Dr. Gant's method of removing rectal cancer through the vagina. This route enabled the operator to remove the growth in a much shorter time than it could be done by the Kraske method, and it restored the bowel function, which was often impossible when there was mutilation of the sacrum, as in the Kraske operation. *Anorectal Operation Under Local Anesthesia.*—The next two reels demonstrated the speaker's method of painlessly operating upon many rectal diseases, including hemorrhoids, tumors, fistula, condylomata, etc. He employed eucaine anesthesia (⅛ of 1 per cent.) in 90 per cent. of his anorectal operations. This invariably produced complete anesthesia within ten seconds and never caused toxic manifestations. He held that it was criminal to administer general anesthesia in this class of operations unless there was some unusual complication, and maintained that surgeons who did not familiarize themselves with the technique of operating under local anesthesia did not deserve to have this class of work referred to them. By watching the expression of patients during operation one was satisfied that they suffered no pain and the technique of the procedure proved that the work was thorough.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Pennsylvania Bureau of Medical Education and Licensure.

July 9-11, 1918.

PHYSIOLOGY, PATHOLOGY, AND BACTERIOLOGY.

1. Outline briefly the postmortem findings following a fatal disease in some particular case under your observation.

2. Describe bone necrosis; also, the method of repair following a fracture.

3. Name the ductless glands, giving the function of each.

4. Give the predisposing causes and the pathology (*a*) of aneurysm; (*b*) of varicose veins.

5. Explain the alteration in function (*a*) in cyanosis; (*b*) in glaucoma.

6. What is meant (*a*) by upper neuron? (*b*) lower neuron? What type of paralysis is characteristic of each?

7. What is the physiologico-pathological significance of Argyll-Robertson pupil? hunch-back? diplopia? nystagmus?

8. By what feature in the investigation are these bacteria identified: gonococci? Klebs-Loeffler bacilli? typhoid bacilli? streptococci? spirochete of syphilis?

9. Name five antiseptics, giving their strength for use and relative value in service.

10. Describe briefly the types of kidney lesions in which the functional capacity of the organ is dangerously impaired. Indicate the findings in uranalysis of each type.

DIAGNOSIS, SYMPTOMATOLOGY, TOXICOLOGY, MEDICAL JURISPRUDENCE

1. What are the symptoms of typhoid fever (*a*) in the first week, (*b*) in the second week? Differentiate typhoid fever from some one confusing disease.

2. Differentiate measles from scarlet fever and name the principal complications of measles.

3. What is meant by loss of compensation in diseases of the heart? What are its main symptoms?

4. What is the significance of bleeding from the mouth? How would you determine its possible sources and causes in three varieties of blood spitting?

5. Differentiate iritis from acute inflammatory glaucoma.

6. Give the symptoms and physical signs of lobar pneumonia and differentiate it from subacute pleurisy with effusion.

7. What are the symptoms of erysipelas? Differentiate it (*a*) from erythema simplex and (*b*) from acute eczema.

8. If poison is found in the stomach contents, what other evidence is necessary to sustain satisfactory proof of death by poisoning?

9. What are the signs of death (*a*) by strangulation? (*b*) by drowning? (*c*) by fractured skull? (*d*) by internal hemorrhage?

10. What are the early symptoms of acute poliomyelitis before paralysis? About when does paralysis occur?

ANSWERS.

PHYSIOLOGY, PATHOLOGY, AND BACTERIOLOGY.

1. *Cerebrospinal Meningitis.*—"In the early stages there is intense hyperemia of the pia-arachnoid; in fulminant cases these may be the only lesions observed. In the ordinary acute cases, there is sero-fibrino-purulent inflammation of the pia-arachnoid, especially marked at the posterior basic region of the brain, and the dorsal surface of the thoracic and lumbar cord; but the exudate may extend to the convexity of the brain, and indeed involve the entire pia-arachnoid. The cranial nerves (especially the second, third, fourth, fifth, sixth, seventh, and eighth) are often embedded in a thick, fibrino-purulent exudate, whereby irreparable damage results. In more chronic cases the pia-arachnoid is irregularly thickened, the ventricles are distended with turbid fluid, and irregular foci of hemorrhage, softening, and encephalitis are encountered. Microscopically the exudate consists largely of polynuclear leucocytes, which contain the meningococcus and certain unusually large endothelial cells; there is also leucocytic infiltration of the brain and cord, foci of hemorrhage and suppuration, and swelling of the ganglion and neuroglia cells. The lesions common to most toxemias are found in the other organs."—(Kelly's *Practice of Medicine.*)

2. "*Necrosis* is the death of a larger or smaller portion of bone. This may be induced by conditions which deprive the bone of its proper vascular supply from the periosteum and medulla. It may be associated with suppurative periostitis, osteomyelitis, and osteitis, traumatic separation of the periosteum, ulcers of neighboring soft parts, emboli, the action of phosphorus vapor, and exhaustive infectious diseases. Necrosis is a form of pure gangrene, differing from gangrene of soft parts in that the dead bone has at first, and may retain for a long time, the general outward characters of the normal bone; while in dead soft parts rapid absorption may occur, or, should bacteria of various forms be present or gain access to the dead tissue, putrefaction, with complex changes, may ensue. When a portion of bone has died, inflammation occurs at the dividing line between the dead and living bone. The inflammation has the characters of a rarefying osteitis, and finally separates the dead from the living bone. The dead bone, or sequestrum, may remain smooth and unaltered, or it may be eroded by the influence of surrounding pus or granulation tissue or osteoblasts. In this way it is possible for the sequestrum, if it be small, to be entirely absorbed. More frequently there is a production of new bone around the sequestrum, either beneath the periosteum or in the substance of the bone, and this becomes lined with granulation tissue, from which pus may continue to be formed, bathing the sequestrum. Necrosis may involve the superficial layers, or the entire thickness of the wall of a long bone, or only the spongy tissue and inner layers, or an entire bone, or a number of different portions of the same bone, but it is most apt to occur in compact bone. The death and separation of the bone may be soon followed by the growth of new bone to repair the loss. The periosteum, the medulla, and the surrounding soft tissues may all take part in this new growth. The new bone is usually irregular, rough, and perforated with openings through which pus formed around the sequestrum may be discharged. If the sequestrum be removed, healing may occur by the formation of new bone, but the bone is usually more or less distorted by the irregular new ossification."—(Delafield and Prudden's *Pathology.*)

"The broken ends of the bone are rough and irregular, and the periosteum is torn more or less, but some portion usually remains as a bridge between the fragments. The soft structures in the neighborhood are lacerated, so that the parts are infiltrated with blood-clot, which fills up the spaces between the bone ends. As in repair of any other part, the blood-clot in a few hours is infiltrated with leucocytes, whose duty it is to absorb the clot. The connective-tissue cells in the surrounding parts proliferate, and the bone undergoes rarefying osteitis, so that the place of the blood-clot is taken by granulation tissue. The granulation tissue becomes calcified, and the calcified tissues ultimately replaced by bone. The periosteum plays a large part in the ossification of the new tissue. It becomes stripped up for some distance, hyperemic, and thickened. Granulation tissue is formed from it, and unites with that which has replaced the blood-clot. This mass binds the bone together and forms the *provisional* or *ensheathing callus*, which is subsequently ossified by the growth of the periosteal osteoblasts spreading over the mass. The medulla becomes plugged with granulation tissue or *internal callus*, and this, as well as the granulation tissue lying between the fragments of compact bone, becomes ossified, the bone cells of the compact tissue probably proliferating to take part in the repair."—(*Aids to Surgery.*)

3. The *ductless* glands are: The spleen, thymus, thyroid, parathyroids, suprarenals, carotid, coccygeal, pituitary, and pineal glands.

The function of the spleen: The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin.

The function of the thyroid is not definitely settled: (1) It has some trophic function, regulating oxidation in the body, and it is supposed to have also a special influence on the vasomotor nerves, the skin, the bones, and on the sexual functions; (2) it is supposed to antagonize toxic substances, and (3) it produces an internal secretion.

The function of the thymus is not settled; it is said: (1) To be a blood-forming organ; (2) to have influence on growth and nutrition; (3) in hibernating animals it is supposed to store up materials which can be utilized during the period of inactivity.

The function of the suprarenals is not definitely settled; they produce an internal secretion which is probably necessary to life. This secretion causes constriction of arterioles, raises blood pressure, and stimulates muscle fibers which are supplied by the sympathetic system. There is supposed to be some connection between the adrenals and the thyroid and pituitary bodies.

The function of the pituitary body: Complete removal of whole gland or of anterior lobe is followed by death; the anterior lobe is connected with growth; if the gland hypertrophies there follows overgrowth of the skeleton, and partial removal leads to failure of development of the body as a whole and of the sexual glands. The posterior lobe is believed to cause constriction of arterioles, rise of blood pressure, contraction of the involuntary muscles in many viscera, increased flow of urine, an increased secretion of milk.

The function of the *other* ductless glands is unknown. They all, or nearly all, furnish an internal secretion.

4. An *aneurysm* is a pulsating sac containing blood, and communicating with the lumen of an artery.

A *true aneurysm* is one in which the sac is composed of one or more of the coats of the artery.

A *false aneurysm* is one whose sac contains no arterial coat, but is formed of condensed perivascular tissue.

Predisposing causes: Atheroma, syphilis, old age, arteritis, alcoholism, male sex.

Structure: The *sac* consists more or less evidently of a distention of all or part of the original walls of the vessel while it is small; but as the aneurysm increases, the original structure is replaced by a mass of newly formed fibrous tissue, due to a condensation and matting together of the surrounding structures, with or without an internal lining of laminated fibrin deposited on parts where the endothelium has disappeared. The *contents* of the sac depend on the character, age, and size of the aneurysm. While still small and with a complete endothelial lining, it contains fluid blood; but as the tumor grows, and especially if of the sacculated type, fibrin is deposited in layers which gradually encroach on the cavity, and may in time completely fill it, so that in rare cases a spontaneous cure results. The oldest laminæ are dry and yellowish-white in color; those more recently deposited are softer and more reddish, while the last formed is merely like ordinary blood coagulum. No single lamina covers the whole area, but layer is arranged over layer in such a manner that the oldest and necessarily the smallest laminæ are nearest to the sac wall.

Varieties: There are three forms: (1) *Sacculated aneurysm* is one in which the dilatation springs from one side of the artery only, and in which the sac communicates with the artery by a comparatively narrow opening. (2) *Fusiform aneurysm* is due to a general dilatation of the whole circumference of an artery. Its progress is slower than that of the sacculated variety, and there is little or no laminated clot at first. It usually ends in the formation of a sacculation at one part. (3) *Dissecting aneurysm* is due to blood getting into the middle coat and stripping it up. It cannot be recognized during life.

Varicose Veins.—A vein is varicose when it is dilated, elongated, and tortuous. The veins commonly affected are the superficial veins of the leg. Other common situations are the hemorrhoidal plexus—piles; and the pampiniform plexus—varicocele.

Causes.—Anything which induces prolonged distension of veins, such as long standing, pressure of tight garters, pressure in the pelvis from pregnancy or tumors, occlusion of the deep veins, may cause varix. An abnormal communication between an artery and a vein will produce distention of the vein, as in aneurysmal varix. Congenital overgrowth of veins, or tendency to the development of varix, is a contributing factor.

Pathological Changes.—Before the actual development of varicosity, the walls are weakened by chronic inflammation. The elastic coat is replaced by fibroid tissue, so that the wall is no longer able to resist the pressure of the blood from above, and consequently dilatation occurs and the valves become incompetent. The veins also elongate, and therefore become tortuous. The pressure of the column of blood from above is the chief factor in bringing about the dilatation.—(*Aids to Surgery*).

5. *Cyanosis*.—"Cyanosis commonly attends dyspnea and is due to like causes, to a deficiency of oxygen and an excess of carbon dioxide in the blood. Dyspnea, however, may occur without cyanosis, as in uremia, and cyanosis may be present without dyspnea, as in congenital heart disease. Cyanosis is common in diseases of the lungs, interfering with proper oxygenation of the blood, and may result from obstruction to the entrance of air into the lungs, to restriction of the available breathing surface of the lungs, and to weakness of the respiratory muscles and nerves. It occurs also in disease of the heart, in erythremia, in chronic acetanilide, and other coal-tar poisonings, and in so-called enterogenous cyanosis."—(Kelly's *Practice of Medicine.*)

Glaucoma.—"A current normally passes from the ciliary body, around the lens, through the pupil, anterior chamber, and ligamentum pectinati in the iris angle, into Schlemm's canal. Interference with this system of circulation, such as would be caused by blocking-up of the iris angle and cutting off the outflow, with or without increase in the secretion, will be followed by rise in intraocular tension. Upon this theory most explanations of glaucoma are founded."—(Alling and Griffin's *Diseases of Eye and Ear.*)

6. The *upper motor neuron* leaves the Rolandic area of the cortex and passes through the corona radiata, internal capsule, crus, pons, medulla, and pyramidal tracts to terminate in the posterior horn of the spinal cord.

The *lower motor neuron* begins in the cells of the anterior horn of the spinal cord and leaves by the ventral root to end in a peripheral nerve.

Hemiplegia is characteristic of the upper neuron paralysis.

Paraplegia is characteristic of the lower neuron paralysis.

7. *Argyll-Robertson* pupil generally indicates a lesion of the optic tract or Meynert's fibers.

Hunchback or kyphosis indicates disease or injury of the spinal column; it is an anteroposterior curvature.

Diplopia indicates defective action of the ocular muscles or injury at base of brain or the toxic action of certain drugs.

Nystagmus indicates bilateral spasm of the ocular muscles.

8. *Gonococci* are recognized as diplococci, generally within the pus cells, and decolorized by Gram's stain.

Klebs-Loeffler bacilli are the only Gram positive bacilli usually found in the mouth.

Typhoid bacilli will give the agglutination test (Widal's) after the tenth day.

Streptococci are recognized by the cocci being arranged in chainlike groups.

Spirochete of syhpilis is recognized by using a dark field condenser (in the living state), or by examining smears stained with Giemsa's solution, when the spirochete takes on a violet or reddish tinge.

9. Five Antiseptics: (1) *Carbolic acid,* generally used in solutions of 1 in 40 or 1 in 20; it is useful for emergency work, is irritating to sensitive skins, some people are particularly susceptible to its action, it is readily absorbed, and may produce dark colored urine.

(2) *Corrosive sublimate,* usually employed in solutions of 1 in 2000, 1 in 1000, or 1 in 500; it is reliable, has less penetration than carbolic acid, and is less roughening to the skin; it is irritant if applied for too long a time, and is not suitable for instruments.

(3) *Biniodide of mercury* is a powerful antiseptic, chiefly employed in a 1 in 500 solution in 70 per cent. methylated spirit, for use on the skin of the patient or the hands of the surgeon; it is very toxic; a 1 in 2000 aqueous solution is also used for the hands.

(4) *Boric acid* is a weak and mild antiseptic, used in saturated solution when stronger antiseptics are inadvisable; employed in the eye and for infants.

(5) *Lysol,* used in a 2 per cent. solution, used for syringing out cavities, external ear, etc.

10. Tests of the functional activity of the kidneys are of value in renal, cardiorenal, and cardiac diseases. In *acute nephritis,* frequent repetitions of the test are necessary, since marked renal functional changes occur with considerable rapidity. In *mild chronic nephritis* the excretion of the dye is but little reduced, while in *severe nephritis* it is markedly decreased or even suppressed. Marked diminution or suppression usually occurs in *uremia,* and impending uremia is frequently indicated, when routine clinical and urinary studies give no suggestion of it. *Passive congestion* only affects the phthalein output when of a severe grade, and slight circulatory improvement is associated with prompt improvement in the phthalein excreted.—(From Osler and McCrae's *Modern Medicine.*)

DIAGNOSIS, SYMPTOMATOLOGY, TOXICOLOGY, MEDICAL JURISPRUDENCE.

1. Typhoid Fever.—"During the *first* week there is in some cases (but by no means in all, as has long been taught) a steady rise in the fever, the evening record rising a degree or a degree and a half higher each day, reaching 103° or 104°. The pulse is rapid, from 100 to 110, full in volume, but of low tension and often

dicrotic; the tongue is coated and white; the abdomen is slightly distended and tender. Unless the fever is high there is no delirium, but the patient complains of headache, and there may be mental confusion and wandering at night. The bowels may be constipated, or there may be two or three loose movements daily. Toward the end of the week the spleen becomes enlarged and the rash appears in the form of rose-colored spots, seen first on the skin of the abdomen. Cough and bronchitic symptoms are not uncommon at the outset. In the *second week*, in cases of moderate severity, the symptoms become aggravated; the fever remains high and the morning remission is slight. The pulse is rapid and loses its dicrotic character. There is no longer headache, but there are mental torpor and dullness. The face looks heavy; the lips are dry; the tongue, in severe cases, becomes dry also. The abdominal symptoms, if present—diarrhea, tympanites, and tenderness—become aggravated. Death may occur during this week, with pronounced nervous symptoms, or, toward the end of it, from hemorrhage or perforation. In mild cases the temperature declines, and by the fourteenth day may be normal."—(Osler's *Practice of Medicine.*)

It may be confused with malarial (remittent) fever. The following table is taken from an elaborate one by Thayer:

TYPHOID FEVER	MALARIAL (REMITTENT) FEVER.
Blood shows no leucocytes; eosinophiles diminished or absent; serum causes agglomeration of typhoid bacilli; malarial parasites and pigment absent.	Blood shows no leucocytosis; eosinophiles not notably diminished; serum does not cause agglomeration of typhoid bacilli; malarial parasites and pigmented leucocytes present.
Fever uninfluenced by quinine.	Fever disappears under quinine.
Usually epidemic; prevailing commonly in cities.	Is an endemic disease occurring particularly in rural districts; rarely epidemic.
Anemia absent, excepting in later stages.	Anemia more or less marked early in the course.
Characteristic roseola.	No characteristic exanthem; urticaria not uncommon.
Has a fairly characteristic course.	No distinct course.
Urine high-colored; bile absent; Ehrlich's diazo-reaction present during the height of the process.	Urine high-colored; may show a trace of bile; Ehrlich's diazo-reaction rarely present.
The temperature does not reach 40° C. (104° F.) before the third or fourth day.	The temperature may arrive at 40° C. (104° F.) within twenty-four hours.
The apathetic expression of the face, the dryness of the tongue, and sordes upon the teeth are well marked and progressive.	These symptoms are not very marked.
Herpes rare.	Herpes common.

2. *Scarlet fever:* Period of incubation, from a few hours to seven days. Stage of invasion, twenty-four hours. Character of eruption, a scarlet punctate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes. The eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type, the lymphatics in the neck may be swollen, and there is sore throat; Koplik's spots are absent.

Measles: Period of incubation, ten to twelve days. Stage of invasion, four days. Character of eruption, small dark red papules with crescentic borders, beginning on face and rapidly spreading over entire body; desquamation is branny. The eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present; Koplik's spots are present.

Complications of measles: Catarrhal pneumonia, gastroenteritis, conjunctivitis, otitis.

3. "The alteration in the systemic blood supply caused by the valvular defects of chronic endocardial inflammation are such that, if continued, the integrity of the body is threatened. To overcome the impaired functions of the valves and to maintain the general circulation, the heart increases in size and strength (*compensatory hypertrophy*). The period in which this occurs is called the *period of compensation;* its duration is indefinite. It may be recognized by the physical signs of valvular disease without any symptoms of disturbed circulation. Anything which disturbs the equilibrium as it now exists, such as acute diseases and excessive work, leads to *ruptured compensation*, a condition attended by cyanosis, dyspnea, edema, gastric, hepatic, and renal disturbances, and often death."—(Hughes' *Practice of Medicine.*)

4. *Bleeding from the mouth* may be due to:

(1) *Local causes* such as stomatitis, spongy gums, adenoids, biting of tongue, nose-bleed with escape of blood into pharynx, and certain blood affections (scurvy, purpura, etc.).

(2) *Hemoptysis*, which may be due to traumatism; certain organic diseases of the lung, especially to tuberculosis, lobar pneumonia, bronchiectasis, gangrene, infarct, and cancer. Passive congestion, the result of heart disease, especially mitral lesions; rupture of aortic aneurysm; diseases profoundly affecting the blood, such as purpura, hemophilia, scurvy, and leucemia; ulcers, traumatic, syphilitic, or malignant of the trachea or larynx.

(3) *Hematemesis*, which may be due to traumatism; gastric ulcer; gastric cancer; venous engorgement of the stomach following cirrhosis of the liver, primary splenomegaly, or chronic heart disease; acute gastritis; blood dyscrasia, as in scurvy, purpura, severe infections, and grave anemias; rupture of aneurysm; swallowing of blood from nose, mouth, or throat.

When the bleeding is due to local causes, inspection generally shows its source. Hemoptysis and hematemesis may be differentiated as follows:

HEMATEMESIS.	HEMOPTYSIS.
1. Previous history of gastric, hepatic, or splenic disease.	1. Previous history of pulmonary troubles.
2. Blood is vomited.	2. Blood is coughed up.
3. Blood is dark colored and not frothy.	3. Blood is frothy and bright red.
4. Blood may be mixed with food.	4. Blood may be mixed with sputa.
5. Giddiness or faintness usually precedes vomiting.	5. Sensation of tickling in the throat usually precedes.
6. Nausea and weight in epigastrium.	6. Dyspnea and pains in the chest.
7. Often followed by melena (black, tarry stools).	7. Is not usually succeeded by melena.

—(Hughes' *Practice of Medicine.*)

5.

	GLAUCOMA.	IRITIS.
Age	Over forty.	Any.
Tension	Plus.	Normal.
Congestion	General, especially scleral.	General, especially circumcorneal.
Cornea	Cloudy and steamy surface.	Cloudy.
Anterior chamber	Shallow.	Unchanged.
Pupil	Dilated, oval.	Contracted, synechiæ.
Pain	Severe, continuous.	Especially at night.
Vision	Much reduced.	Somewhat reduced.

—(From Alling and Griffin's *Diseases of the Eye and Ear.*)

6. *Symptoms and physical signs of lobar pneumonia:* "*Inspection* reveals during the first stage deficient movement of the affected side, due to pain. The apex-beat is normal in situation, and the interspaces do not bulge. In the second stage the healthy side rises normally, the affected side lagging behind. If both lower lobes are impervious to air, the diaphragm cannot descend and the epigastrium does not project during inspiration, the breathing being conducted by the upper part of the chest (superior costal respiration). *Palpation* during the first stage shows the vocal fremitus to be more distinct than normal, especially over the diseased portions. In the second stage, the vocal fremitus is markedly exaggerated, except in those rare instances of occlusion of the bronchi by secretion. The cardiac impulse is felt in the normal position. *Percussion*—In the first stage, the percussion note is slightly impaired at times, having a hollow or tympanitic quality. In the second stage there is dullness over the affected parts, with an increased sense of resistance. Over unaffected adjoining areas the resonance is increased (Skoda's resonance). *Auscultation*—In the first stage there is heard over the affected part a feeble vesicular murmur, associated with the true vesicular or crepitant (cracking) râle, heard at the end of inspiration only. In the second stage there is a harsh, high-pitched, bronchial respiration, at times resembling a to-and-fro metallic sound, except in those rare instances in which the bronchi are more or less filled with secretion. Bronchophony, or distinctly transmitted voice, is present and at times pectoriloquy, or distinct transmission of articulated sounds, may be heard. In the third stage the breathing changes from bronchial to bronchovesicular and the crepitant râle (crepitation redux) returns. As resolution proceeds, the breath sounds are associated with large and small moist and bubbling râles."—(Hughes' *Practice of Medicine.*)

PLEURISY WITH EFFUSION.	LOBAR PNEUMONIA.
Onset marked by chilliness persisting for a few days.	Onset acute, with rigor, lasting one hour or longer.
Cough is irritating; no expectoration, or, if present, catarrhal in character.	Cough more marked, and accompanied by rusty or bloody, tenacious expectoration.
Sputum negative; tubercle bacilli rare.	Dense aggregations of pneumococci present.
Moderate fever of continuous type; declines by lysis.	Fever, 102° to 104° F.; falls by crisis.
Prostration moderate.	Prostration extreme.
Unilateral distension of the thorax.	Absent.
Countenance pale and anxious.	Mahogany-colored flush of cheeks.
Limited expansion at base of chest on the affected side.	Degree of expansion slightly, if at all, inhibited.
Tactile fremitus diminished or absent.	Increased over area of consolidation.
Interspaces bulging at base of chest.	Absent.
Percussion shows flatness, with great resistance to the pleximéter finger.	Dullness with less resistance, and sometimes a tympanitic note.
Diminished or absent breath-sounds over effusion the rule. Respiration murmur diffuse, distant, and generally unaccompanied by râles. Bronchial breathing may be present over the entire affected side of the chest.	Harsh bronchial breathing and presence of râles in first and third stages, unless a bronchus is plugged.
Friction sound heard in early and late stages.	No friction murmur; râles present.

—(Anders and Boston's *Medical Diagnosis.*)

7. *Symptoms of erysipelas:* The disease is usually ushered in with a chill, malaise, anorexia, headache, and elevation of temperature (102° to 105° F.). The erysipelatous eruption is highly characteristic. The affected area is sharply defined, of a shining crimson or violaceous hue, elevated above the surrounding skin, and firm, hot, and tender to the touch. In addition, vesicles or blebs are prone to develop. The patient complains of pain, burning, or itching. The eruption tends to spread by peripheral extension, the older parts first undergoing involution, the maximum of inflammation being found at the periphery. In any one locality it runs its course in four or five days, ending in desquamation. The disease, however, may last for weeks, owing to constant extension. Albuminuria may be present. There is marked leucocytosis.

Erythema simplex is characterized by nonelevated, variously sized and shaped patches of redness. Redness is the essential characteristic of the disease. It may be a bright or a dull red, but always disappears upon pressure. Infiltration and elevation are absent. Mild burning and itching are usually present.

ERYSIPELAS.	ECZEMA ERYTHEMATOSUM.
1. Sudden onset with chill and marked constitutional symptoms.	1. No constitutional symptoms.
2. Eruption sharply marginated.	2. Fades into surrounding skin.
3. Glazed, shining surface; great edema.	3. Dull, scaly surface; Slight infiltration.
4. Color, violaceous.	4. Bright or dull red.
5. Burning pain.	5. Itching more marked.
6. Occurrence of discrete vesicles or blebs.	6. Vesicles occur in patches, if at all.
7. Progressive peripheral spreading.	7. Spreading irregular.
8. Runs an acute course.	8. Course, chronic.
9. Contagious.	9. Not contagious.

8. If poison is found in the stomach contents, it is also necessary to prove (1) the absence of other causes of death; (2) the presence of the symptoms, during life, known to be caused by the poison; and (3) the presence, on autopsy, of such lesions as are known to be produced by the poison. Without these, death by poisoning cannot be proved.

9. *In death by drowning:* The surface is pallid, the face appears tranquil, the eyes and mouth being partly open. The skin often has the appearance known as gooseskin, and, if the body has lain upwards of twelve hours in the water, that of the hands and the feet is sodden by imbibition. The most important external sign is the presence on the mouth and nostrils of a fine froth (possibly blood stained), composed of air, mucus, and the medium in which drowning took place; if the body remains three or four days in water, the froth disappears. Exceptionally, fragments of weeds or other small objects may be found tightly grasped in the hands. On opening the thorax the lungs, gray in color, with reddish staining, are seen to be very voluminous, a condition known as ballooning, partly due to infiltration of the lung tissue with some of the medium in which drowning took place, and partly to true edema. The lung substance is inelastic and pits on pressure. On section, fluid and froth resembling that found on the lips exude from the divided air passages. Minute subpleural hemorrhages are not infrequently present, and the pleural cavities may contain fluid. The stomach often contains water or other liquid which was involuntarily swallowed during attempts at respiration. Occasionally some of this fluid is forced by vital action into the intestines. With one exception, the remaining appearances are those met with after death from asphyxia. The exception is constituted by the blood, which is not only dark colored and fluid, as is usual after death from asphyxia, but is also diluted by the imbibition of water from the stomach and lungs.

In death by strangulation: The blood is of a dark color, owing to complete reduction of the hemoglobin. The proportion of carbonic acid is increased, and owing to its excess the blood coagulates slowly or imperfectly; hence it remains fluid or forms few and soft coagula. The large veins, the pulmonary artery, and the cavities of the right side of the heart may be distended with dark fluid blood, but this is by no means necessarily the case. The left side is usually empty or nearly so.

The lungs may be congested, but are often pallid and anemic, though the dependent parts usually exhibit appearances of hypostatic engorgement. The abdominal viscera, especially the kidneys, are often congested. The appearance of the brain varies; it may be anemic or more or less congested. Special signs characterize special modes of causation of asphyxia. Very commonly punctate ecchymoses are visible on the conjunctiva, face, neck, and chest. They are considered by Tardieu to be more frequent in strangulation than in asphyxia from other causes, or than in cases of overstraining, which likewise may lead to them. In the subcutaneous cellular tissue, and in the fascia of the muscles above and below the hyoid bone extravasations are frequently found, as well as on the external surface of the thyroid cartilage and trachea. The lungs vary as regards their vascularity; but on the surface it is common to find pseudomembranous patches, which are due to the rupture of some of the superficial air cells and collection of air bubbles under the pleura. In the substance of the lungs congested patches, or apoplectic extravasations, are often found, varying in size, but larger than those usually found in suffocation.—(From Quain's *Dictionary of Medicine.*)

In death by fractured skull, signs of a recent fracture will be found, with blood in the site of the fracture; possibly there will be blood or cerebrospinal fluid escaped into tissues, under eyes, in nose, behind ears, etc.; signs of cerebral compression will also be found.

In death by internal hemorrhage, there will be found a wound in a vascular part or in several vessels or in a large vessel, and the veins in the neighborhood will be found empty. There will be absence of signs of fatal disease; and blood will be found in the body cavities and tissues.

10. *Acute Poliomyelitis.* The onset is sudden, and is marked by fever, vomiting, convulsions, headache, restlessness, pain in the bones and muscles. Paralysis sets in in the course of a day or two; the lower extremities are chiefly affected.

(*To be concluded.*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE SURGICAL CLINICS OF CHICAGO, August, 1918. Volume II., No. 4. 893 pages. Illustrated. Price, $10.00 a year. Published Bi-Monthly by W. B. Saunders Company, Philadelphia and London.

ROENTGEN DIAGNOSIS OF DISEASES OF THE HEAD. By Dr. ARTHUR SCHÜLLER. 305 pages. Illustrated. Price, $4.00. Published by C. V. Mosby Company, St. Louis, Mo.

DISPENSARIES. By MICHAEL M. DAVIS, JR., Ph.D., and ANDREW R. WARNER, M. D. 438 pages. Illustrated. Price, $2.25. Published by The Macmillan Company, New York.

ABSTRACTS OF WAR SURGERY. Prepared by the Division of Surgery, Surgeon-General's Office. 434 pages. Price, $4.00. Published by C. V. Mosby Company, St. Louis, Mo.

TUMORS INNOCENT AND MALIGNANT. By SIR JOHN BLAND-SUTTON, LL.D., F.R.C.S. 790 pages. Illustrated. Price, $7.00. Published by Paul B. Hoeber, New York.

THE NEWER KNOWLEDGE OF NUTRITION. By E. V. MCCOLLUM, M.D. 199 pages. Illustrated. Price, $1.50. Published by The Macmillan Company, New York.

HÆMATOLOGISTS' AID TO MEMORY. By HENRY HAROLD SCOTT. Price, 5 shillings. Published by John Bale, Sons & Danielsson, London.

THE EFFECT OF DIET ON ENDURANCE. By IRVING FISHER, Ph.D. 54 pages. Price, 60 cents. Published by Yale University Press, New York.

GUN-SHOT FRACTURES OF THE EXTREMITIES. By JOSEPH A. BLAKE. 136 pages. Illustrated. Price, 4 francs. Published by Masson et Cie., Paris.

Miscellany.

An Italian Hospital Journal.—Periodicals devoted to the activities of hospitals are by no means new but for the most part they are devoted to statistics, case histories, and the like, differing much in other ways from the ordinary medical periodical. For some years past the Ospedale Maggiore of Milan has conducted a monthly periodical under the title of the institution (*L'Ospedale Maggiore*) devoted in the main to hospital practice in all its aspects, irrespective of locality and published by the Council of the Milan Hospitals. Beginning with the March number the subject matter is classed as follows: a main section on the most urgent of hospital problems which is followed by an article on the instruction of students from study of the wounded soldier. These two papers correspond to original matter in the average journal. The second rubric deals with anniversaries in which we read that on March 9, 1618, one Isabella Varesi, married name Castano, bequeathed 16,594 lire in property to the hospital. This rubric is followed by the monthly current chronicle of events in hospital life in Milan. Incidentally we note many medical data in reference to suicidal attempts, the movement of tuberculous cases, the out-patient services, etc. The entire monthly report of the Maggiore is given. The next rubric refers to legislation as it affects hospital existence. This is followed by a forensic department and this in turn by the proceedings of various hospital councils and their results.

The Federation of University Students in South America.—In Argentine and Uruguay the undergraduates of all universities are said to possess an organization which includes students of medicine, law, engineering, agriculture, veterinary medicine, philosophy, literature, economic science, and presumably others not mentioned. Each class of students has its own center which sends delegates to a central body. The students are also classed by their years of graduation. Club features are numerous, such as libraries, museums, vaccination and medical consultation facilities, university extension, athletics and sports, social gatherings, etc. A correspondent of the *Journal de Médecine de Bordeaux* for August mentions the publication maintained by the university medical students under the name of *Revue du Cercle Medical Argentin et du Centre des Etudiants en Médecine;* he neglects to state whether this periodical is published in French or whether the name is a French translation of the Spanish original. The periodical appears monthly and the number for last October which he reviews contains 236 pages. In addition to numerous original articles on medical subjects there is a department on "University Life" through which the "medic" is kept in touch with all of the activities of students of other subjects. One learns that the medical men won the annual football championship over the legal and other student bodies. Among miscellaneous subjects agitated was one in reference to the propriety of admitting foreigners to the hospitals. There was an account of a journey of students of Buenos Ayres to Montevideo, as guests of the Uruguayan students.

NERVOUS DISTURBANCES OF THE CIVIL POPULATION IN WAR TIME.

BY J. LEONARD CORNING, M.D., LL.D.

NEW YORK.

ALTHOUGH much has already been said and written concerning the mental and physical sufferings of the civil population in those countries overrun by the enemy in the great war, there appears to be a scarcity of commentary regarding the nervous disturbances more or less prevalent among the inhabitants of those allied countries wherein the Central Powers have been unable to set foot.

True, there have been sabotage, intrigue widespread and disquieting, petty treason, enough to provoke lynchings here and there, and a propaganda at once so insolent and insidious as to engender a sense of exasperation that neither ultimate victorious peace nor yet the flight of many years is likely to dull, much less eradicate.

These disclosures of low cunning and cruelty near at hand with the chronicle of perfidy and oppression characterizing the advance of the armies of the Central Powers abroad have aroused in the breasts of the people of this country a degree of detestation and loathing impossible to exaggerate; so that, at the present time, it has been aptly said that only knaves, traitors, or flabby-witted visionaries are to be caught mumbling a stealthy extenuation.

While these feelings of abhorrence not unmixed with a vehement desire for retribution pervade the nation as a whole, their effects are by no means everywhere the same. Upon the vigorous young men of the country, more especially those who have volunteered or been drafted into the service afloat or ashore, there is unmistakable light-heartedness, tempered, it is true, with a certain seriousness, offspring of a realization of the tragic elements of the enterprise to which they are committed. Not in a single instance have I heard a regret expressed at the imminence of the departure for France; all, so far as my observations extend, are fired by a single desire: to be off and doing as quickly as possible, or as they spice the vernacular, to "get a crack at the Hun."

Of a distinctly different character are the psychical phenomena observable in those of middle age or advanced life. Among these individuals, especially those of a high degree of emotionality and intelligence and well-informed, perhaps, as to the past and contemporary history of Prussia, indignation at her barbarities and ruthless spoliations attains such intensity as to amount to something not far removed from obsession. Some of them seek relief in war work, through the Red Cross and other recognized agencies; while others, innocent theretofore of creative endeavor, busy themselves with contrivances to circumvent the submarine, or cause the undoing of the enemy on the battlefield by inventions impracticable, more or less.

It is both idle and pedantic to endeavor to build up a novel clinical entity from the neurotic phenomena disclosed by these persons. The symptoms found in them are, on the whole, those met with wherever a powerful emotion fails of appropriate motor realization. Unable to get to the field of combat; debarred from delivering a thrust or firing a shot, their indignation pent up, futile, they become the victims of morbid brooding, depression, irritability, and insomnia, to which the varying fortunes of battle and the uncertainties of business or the economic situation as a whole lend a further and by no means insignificant aggravation.

This enhancement of erethism, though not identical in all respects with that found in gamblers, bears a sufficient resemblance to it to suggest some measure of analogy.

In the gambler the rapidity of the alternation between hope and fear is the chief source of the pernicious excitement; whereas in war the lapse of time between a victory and a defeat is incomparably longer, and the duration of exhilarating or depressive emotions proportionately lengthened. Moreover, there is the added, and continuous, suspense consequent upon the question as to the final issue of the war as a whole, and this to some extent, if not entirely, irrespective of the individual victories or defeats.

The subjoined diagrams will help to an appreciation of what is meant.

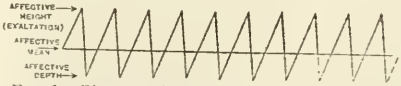

FIG. 1.—Diagram showing suspense curves in gambling. Note that the height is somewhat greater than the depth, and that there is no logical termination, the erethism continuing after cessation of play.*

FIG. 2.—Diagram showing suspense curve in war. The curve, following the infrequent rotation of mood, is longer, and, at the same time, more flattened. It is, moreover, necessarily irregular, in accordance with the vicissitudes of the conflict.

No comprehension of the nervous disorders of the civil population during war is possible without some

*Taken from the writer's paper on "The Psychology of the Gambling Habit—A Study of Suspense in Gaming, the Drama, and the Experimental Sciences," MEDICAL RECORD, November 30, 1912.

understanding of the major emotions involved in its pursuit. Without question, anger is the emotion that looms high above the rest. Whether one party to the conflict, the most uncouth, the most egoistic, the most mendacious in all Europe, be bent upon the domination of its more civilized neighbors, while these, outraged by the wholly unwarranted aggression, take up arms in the defence of their invaded territories, the result in both instances, so far as this emotion is concerned, is the same.

True, in the first event the arousement of the passion springs from an ignoble motive; while, in the second, its genesis is justified a hundred fold. Still, whether engaged in by a bandit nation, supporting its greed and aggression by turning in its own behalf the elementary principles of morality upside down; or whether undertaken by civilized peoples resisting such a barbarous attack upon their liberties and territory to the uttermost, anger as a major constituent of the mental state of both the civilians and soldiery is never lacking.

Regarded as an internal and purely psychical phenomenon, anger is refractory to retrospective analysis. Though largely painful, it does not belong wholly in the category of the painful emotions. At its inception, no doubt, it is entirely painful; but, with the coming of the offensive (motor) reaction it is rather pleasurable than the reverse. This is important in a clinical sense; for, as already intimated, it is the indefinite prolongation of the first or painful stage of anger, coupled with the consciousness that the realization of the second, or aggressive stage is impossible, which constitutes in such full measure the nervous strain borne by the civil population in time of war.

Being inaccessible, or largely inaccessible, to retrospection, it is obvious that the psychology of anger is to be sought for in its evolution.

In animals, especially those who live by tooth and claw, there are no inhibitory forces. Here, if anywhere, the emotion occurs in its purity, its physiological incentive being, for the most part, the appeasement of hunger involving the capture and killing of prey. Linked with, or rather dependent upon, an instinct so rudimentary as nutrition, the feeling is characterized by amazing violence, a violence which has been well compared to some titanic outbreak of nature, sudden, irresistible, like the eruption of a volcano.

Something of the kind is also seen in undeveloped human beings—children and savages, uncouth peoples, and idiots—in whom the outburst, with consequent acts of cruelty, is accompanied by feelings of pleasure. Instances of this kind of unbridled cruelty and anger disclosed by the *adult* have been afforded by the present war, especially during its initial stages, at the time when hordes of brutal, degenerate Teutonic soldiery overran Belgium and northern France. These outrages, for the most part, were perpetrated against the defenseless—old men, women, children. (See the Bryce report and other authentic evidence.)

The anger typical of civilized peoples is, on the whole, radically different from all this. Beginning in hatred or resentment at insult or outrage, the aggressive act, through the inhibitory intervention of the intellect, is postponed until judgment proclaims the time favorable for fulfillment. An instance in point is seen in the recent advance of the Belgian army. The last forlorn remnant of the military forces of a brave little country treacherously overrun; its inhabitants subjected to pillage and unutterable outrage, there arose and grew in the breasts of this soldiery a rancor that neither time nor the hardships of the trenches could allay.

Deliberately, tirelessly, they prepared themselves for the reckoning, increasing their numbers as they could, and adding little by little to their equipment. At length there came a day when Retribution, held back through all the years, leaped from the trenches. A call from their king, and these Belgian heroes fell upon the enemy, to overcome in a kind of frenzy of valor obstructions heretofore deemed impassable. Onward, mile upon mile, they fought their way, wreaking bloody vengeance; while their captives, sodden-faced, thick-jawed louts, shuffled in thousands to the rear.

Various attempts have been made to differentiate normal from pathological anger. It has been said, on the one hand, that normal anger as we see it in civilized races is a fugitive phenomenon, unaccompanied by detriment to the organism; while, on the other hand, its pathological manifestation is the direct reverse of this. Such distinctions are obviously difficult to draw in practice, although the extreme cases are easily recognizable. Of greater value is the test based on the presence or absence of adquate motive. Judged by this standard, the indignation of Belgium had a sufficient motive, and the like may be said of Servia and France.

While anger in its usual manifestations is of brief duration, the same, as we have seen, cannot be said of the feeling when aroused in war time. Hence, to apply at such a crisis the test of duration, with a view to determining whether anger is "normal," or the reverse, seems far-fetched, to say the least.

The physical manifestations of anger—distention of the veins of the face, increase of the cutaneous circulation (or sometimes extreme pallor); dilated nostrils, with labored circulation; violent, disordered acts of aggression; clenched teeth and increased salivation, are familiar to all. Pulmonary or some other form of hemorrhage may in extreme cases result in death.

Various writers have set down their observations as to pathological phenomena directly traceable to anger. Mention here of the more striking effects must suffice. These are demonstrable more especially in the secretions. Thus the lacteal secretion may be so modified as to exert a poisonous effect upon the nursing infant; or again, the saliva may be altered in such fashion that a bite from an enraged animal or human being may be followed by infection of a serious character, or even death.

One other effect of anger, a psychical one, I venture to mention, the fact that this feeling, more especially as exhibited in war time, exerts a disastrous effect upon creative effort, save in so far as this bears upon the conflict; tends, in a word, to give expression, active more or less, to the dominant emotion. Hence literary, artistic, and even scientific endeavors show remarkable shrinkage in breadth, their votaries finding, for the most part, the themes of their activities in various phases of the struggle. The same may likewise be said of

invention and the application of knowledge in general. However regrettable all this may seem from a purely artistic or idealistic standpoint, its immediate political advantage to the State is undeniable.

Biologically considered, anger is intimately associated with, and, indeed, has its origin in, the instinct of self-preservation, appearing, according to Darwin, as early as the tenth month. With the intellectual inhibitions, and the delegation of certain individual privileges inseparable from liberty with law, the arousement of this feeling with systematized aggression has, by common consent, become more and more associated with the defense and preservation of society as a whole. To imagine that anything so fundamental can be set aside by the shallow mouthings of pacific doctrinaires is to assume that men are quite different from what they are. The most that can be hoped for is that progressive enlightenment shall cause the relegation of the passion to the attainment of justice and right.

Besides the various factors already enumerated that tend to cause neurotic disturbances in the civil population during war time, there are certain others of undeniable significance in the genesis of these disorders.

First among such causative elements is the emotional effect upon parents and relatives, and indeed upon the nation as a whole, consequent upon the sending to the battle fields of Europe of vast numbers of the youth of the country. While the composite populations of the United States have always, under adequate provocation, disclosed martial characteristics of a high order, the spirit of militarism has never been rife among them. Indeed, the fact is well attested that here, as in England, greater store is set by life than in most of the continental countries. Because of this, and thanks to idealistic altruism, so plainly seen to be one of the distinguishing marks of American character, the emotional impact consequent upon the imminent sacrifice of their sons in the flower of manhood is more poignant than in a people of gross, uncouth, and sodden make.

There is, however, one mitigating circumstance peculiar to this war: the consciousness, now virtually universal, that kindliness, justice, freedom, even the most elementary decencies, are at stake; that civilization, laboriously perfected through the centuries, is everywhere threatened, and that death is preferable by far to the domination of a bloated barbarism which neither philosophy, literature, science nor art has been able to soften.

Finally, there is the thought of the morrow—the economic question: What has Fate in store for us at the end of the conflict? Shall we have trouble with the stock market? How are we to make ends meet? And business—shall we have expansion or decline? And so forward through the somber catalog.

It is evident that the nervous disturbances frequently encountered among civilians in this war—the insomnia, irritability, depression, morbid anxiety—demand a certain amount of medical attention. To go forward with intelligence in their management, however, presupposes an adequate acquaintance with the confluence of causes that evoke, perpetuate, and aggravate them. For this reason it has been necessary to go into the etiology of the subject in considerable detail. While the derangements of the nervous system previously noted are those most frequently met with among the civil population in time of war, other and more serious difficulties are not uncommon. Prominent among them is insanity, usually of a depressive type, but not invariably so; and, among somatic symptoms, anorexia with sudden and considerable loss of weight.

In conclusion, the significant fact should be recalled that during the years immediately preceding the entrance of the United States as an active participant in the war mental and nervous disturbances analogous to those occurring among the noncombatants during the course of the subsequent conflict were quite common among the more intelligent elements of the population. Keenly aware that the rights and established institutions of this country were threatened, both from within and without; exasperated beyond endurance by the brazen propaganda, intrigue, and sabotage, as well as by the slaughter of men, women, and children on the high seas, the absence of retributive action at that time wrought havoc with cherished ideals of national honor and esteem.

Only the dauntless valor of our troops in France and the colossal preparations for war now making in this country have served to mitigate in men of vision and understanding the recollection of those days of poignant humiliation.

53 West Thirty-eighth Street.

DEMONSTRATION OF DIPLOCOCCUS MENINGITIDIS IN THE ADENOID TISSUE OF THE NASOPHARYNX.

By J. D. ARONSON, Capt. M.R.C.,

AND

S. A. FRIEDBERG, Major M.R.C.,

BASE HOSPITAL, CAMP DONIPHAN, FT. SILL, OKLA.

AN investigation of an epidemic of cerebrospinal meningitis revealed so many points of interest that, in the opinion of the writers, a detailed report of the findings is warranted.

During the months of November and December, 1917, January and February, 1918, a small epidemic of meningitis developed among the troops stationed at Camp Doniphan, Ft. Sill, Okla. The first five cases occurred in the 110th Ammunition Train within a period of fourteen days. A second focus of the disease manifested itself about three weeks later in the 137th Infantry, an organization located about one and one-half miles from the Ammunition Train. Careful investigation showed that the development of this second focus could be attributed to the frequent visiting of the non-commissioned officers of the Ammunition Train to the 137th Infantry, the organization to which they were originally attached.

A consideration of the aobve circumstances led to the conclusion that the dissemination of the disease was probably due to the presence of a carrier or carriers in the Ammunition Train and a systematic study was undertaken to determine the fact.

Following suggestions made by Drs. Jordan and Mathers, the men of the caisson in which two cases of meningitis had but recently occurred were cul-

tured. The cultures were obtained from the nasopharynx by means of a sterile swab placed upon a wire which was bent at an angle of about 45 degrees. This was introduced through the mouth and passed backwards and upwards into the nasopharynx, care being taken not to touch the tongue or fauces with the swab. Plates of horse blood agar were then inoculated from these swabs and the plates streaked by means of a platinum wire. The inoculated plates were incubated for twenty-four hours at 37° C., and suspicious colonies were picked and stained by Gram's method. Colonies which showed the presence of Gram-negative diplococci were transplanted to tubes of horse blood agar and after twenty-four hours' incubation were emulsified in normal salt solution and macroscopic agglutination carried out, using a polyvalent antimeningococcus serum for that purpose.

The caisson cultured consisted of 126 men and of this number five were found to harbor the meningococcus in the nasopharynx. Of the five found positive, three were found in one tent, while the remaining two were found to be quartered in adjacent tents. The following questionnaire was then prepared and data obtained from meningitis cases upon their admission to the Base Hospital and from carriers and contacts in the field:

BASE HOSPITAL, CAMP DONIPHAN.
Fort Sill, Okla.
....., 1918

Name Color Nativity
Age Organization Date of Joining
Previous organization Date of Joining
Date when taken sick
Date admitted to the hospital

Names and addresses of friends in common with previous case of meningitis
Condition of nasopharynx
Home address.
Date when last home
Cases of meningitis in home town
Proximity to cases in home town
Laboratory results:
Spinal fluid
Nasopharynx

As a result of a study of these questionnaires it was found that Pvt. R. R. (one of the carriers found on January 4, 1918) was a friend in common of the following men who developed meningitis on the dates indicated:

Pvt. R. V., November 6, 1917.

Pvt. C. C., November 9, 1917.

Pvt. B. C., November 13, 1917 (in the same drill squad).

Pvt. A. C., November 20, 1917 (quartered in a nearby tent).

While this study was being made, Pvt. H. F. developed meningitis on December 24, 1917, and it was found that he was a tent mate of Pvt. R. R. It was at this time that the entire caisson was cultured, with the result that Pvt. R. R. and two of his tent mates were found to be meningococcus carriers.

In view of the foregoing findings it was considered probable that Pvt. R. R. was the source of the meningococcus infection. This was further borne out by the fact that following his removal from his organization on January 6, 1918, no new cases appeared until February 1, 1918, at which time the last case that occurred in his organization developed.

The following data has been collected as a result of our studies:

Pvt. R. R., age 23, white, farmer by occupation.

Now attached to Caisson F, 110th Ammunition Train.

Previous Medical History: Had measles at age of 11 and pleurisy at 22. His health had otherwise been good with the exception that he had always been subject to catarrhal affections of the respiratory tract.

Family History: Negative.

Personal History: He was born at Carthage, Mo., in 1894, where he attended public school until he was 16. In 1900 he went to Butler, Mo., where he remained until 1906, when he removed to Garden City, Kans. From 1912 to 1914 he worked on a farm at Ft. Collins, Col. He returned to Garden City in 1914, where he remained until he was drafted into the army on September 18, 1917.

During his stay at Fort Collins, Col., he made the acquaintance of a family, which he visited frequently. About one month after his first visit two children in this family developed meningitis and died. These are the only cases of the disease of which he has knowledge prior to his entry into the service.

In September, 1917, he was sent to Camp Funston, Kan., where he was assigned to Co. I, 353d Infantry. While there he was quartered in a barrack with about 150 to 200 men. According to statements made by comrades who were quartered with him, cases of meningitis developed in his barrack as well as in some of the adjoining barracks.

Present History: He was transferred to Caisson F, 110th Ammunition Train, stationed at Camp Doniphan on October 18, 1917. About two weeks after his arrival he complained of weakness in his legs, backache, anorexia, tinnitus aurium in the left ear and pain radiating from his neck to his head. This headache was increased by lateral movement of the head. The backache was relieved by medication, but the headache was persistent. After about three weeks the symptoms disappeared with the exception of the tinnitus. The Regimental Surgeon did not consider his condition serious enough to transfer him to the Base Hospital, nor to keep him in quarters. From the foregoing symptoms one would be hardly justified in the belief that Pvt. R. R. suffered from an attack of meningitis which resulted in his becoming a persistent carrier.

Physical Examination: General inspection showed a fairly well developed male weighing about 140 lbs. and measuring 67 inches. His facial expression was rather dull and apathetic. Examination of the chest, abdomen, and extremities revealed nothing abnormal. Upon examination the right naris was found to be free, but the left was obstructed by a deflection of the septum, which reduced the size of the passage to about one-third of the normal. The

tonsils were moderate in size, submerged and pus was forced out on pressure. The nasopharynx showed the presence of a small amount of adenoid tissue. There was no pus in the nose or nasopharynx nor was there any other clinical evidence of accessory sinus disease. With the exception of a retraction of the left drum membrane nothing abnormal was found in the ears. Roentgenographic examination of the sinuses was negative.

A culture taken from the nasopharynx on January 4, 1918, according to the method described above, yielded a pure growth of meningococcus which was agglutinated by a polyvalent antimeningococcus serum in a dilution of 1:400, which was the highest serum dilution used in that test. He was transferred to the Isolation Camp, where local treatment was instituted. Dichloramine-T in paraffin oil and oil of eucalyptol was applied to the nasopharynx and later local applications of silver nitrate were made.

Cultures taken from the nasopharynx on January 10, 14, 19, 22, and 26 were negative, but became positive on January 28, February 2 and 5. Cultures were again negative on February 9, 13, 17, 20, and 27, and again positive on March 2, 1918.

On March 6 he was transferred to the Base Hospital. A culture from the nasopharynx the next day was found positive.

On March 8 the tonsils and adenoids were removed under local anesthesia. Examination of the tonsils after removal showed them to be somewhat hypertrophied, with distinctly enlarged crypts from which pus could be expressed. No meningococci were found in cultures made from the tonsils.

Several small masses of adenoid tissue measuring about 1.5 cm. in diameter were fixed in Zenker's, embedded in paraffin, sectioned and stained with eosin-methylene blue and by Gram's method. Microscopic examinations of the sections of adenoid tissue revealed masses of bacteria upon the free surface of the tissue and small scattered clumps of bacteria throughout the cortex. Upon the free surface were noted areas of superficial ulceration, located about the masses of bacteria, and numerous

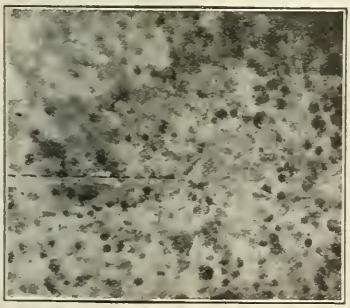

Fig. 1.—Low power photomicrograph showing masses of bacteria deep in adenoid tissue.

newly formed blood vessels were seen at the periphery of the ulcerated areas. The capsule and the trabeculæ were thickened. Tissue surrounding the masses of bacteria deeper in the structure stains uniformly pale and does not show any evidence of inflammatory reaction (Fig. 1). Under higher magnification the masses of bacteria were found to be Gram-negative diplococci with flattened approximating surfaces, resembling morphologically and in their staining reactions the meningococcus (Fig. 2).

Fig. 2.—High power photomicrograph showing a large nest of bacteria and a small clump of bacteria about a blood vessel.

Following the removal of the tonsils and adenoids, no local treatment was instituted, so that the result of the operation could be properly controlled.

The following indicates the result of post-operative cultures:

	Nasopharynx.	Nose.
March 12, 1918	Positive	Negative
March 17, 1918	Negative	Negative
March 20, 1918	Positive	Negative
March 23, 1918	Positive	Negative
March 25, 1918	Negative	Negative
March 27, 1918	Positive	Negative
March 30, 1918	Positive	Negative
April 1, 1918	Negative	Negative
April 5, 1918	Negative	Negative
April 7, 1918	Negative	Negative
April 10, 1918	Negative	Negative
April 14, 1918	Negative	Negative
April 18, 1918	Negative	Negative
May 5, 1918	Negative	Negative

All cultures were made upon horse blood agar, using six plates at each examination. A study of the nasopharynx on several occasions following the operation, while positive cultures were still found, showed an unhealed surface covered by a mucopurulent secretion. The complete healing of this area was followed by constantly negative cultures.

Study of the Cultures: After 24 hours' incubation at 37° C. the cultures obtained from the nasopharynx planted upon defibrinated horse blood agar showed discrete and confluent colonies. The colonies varied in size from 1 to 3 mm. in diameter. They were elevated, moist, round and opalescent in the center, while the margins were clear. The margin of the colony was regular in its outline and sharply limited. After 48 hours' incubation the tendency of the colonies to become more confluent and opaque was noted.

Microscopic examination of the cultures showed them to be Gram-negative diplococci with the morphology of the meningococcus. The organisms showed distinct variation in size and in staining reaction, this being especially marked in 48-hour old cultures.

Agglutination of the organism was carried out, using serum obtained from Pvt. R. R., antimeningococcus serum No. 1, No. 10, No. 30, No. 60, from the Rockefeller Institute and polyvalent antimenin-

gococcus serum. Control tubes were set up using normal horse serum and normal salt solution.

The serum was so diluted that the desired dilution was present in 0.8 c.c. of salt solution and to each tube of diluted serum was then added 0.2 c.c. of an emulsion of a 24-hour old culture obtained from the nasopharynx of Pvt. R. R.

The tubes were well shaken, placed in an incubator at a temperature of 55° C. overnight and readings made the next morning.

The results of the macroscopic agglutinations are here tabulated:

Dilution	Pvt. R. R.	Sera				Controls.		
		No. 1	No. 10	No. 30	No. 60	Polyvalent	Nor. Serum	Salt Sol.

x—Positive. s—Slight agglutination. d—Doubtful agglutination.

Summary.

1. History of cases of meningitis in a community where Pvt. R. R. resided.

2. Sudden outbreak of meningitis in the organization to which he was attached.

3. Close association with four out of a total of six cases of meningitis in his organization.

4. Isolation of a pure culture of an organism showing the cultural, morphological, tinctorial and serological reactions of the regular type of meningococcus.

5. Sudden cessation of cases following his removal from the organization.

6. Demonstration of masses of bacteria in the adenoids removed from the nasopharynx showing the morphological and tinctorial characteristics of the meningococcus.

7. Persistent negative cultures from the nose.

8. Persistent negative cultures from the nasopharynx following the healing of the operative wound.

Conclusions.

1. That the epidemic which made its appearance in the 110th Ammunition Train was due to a carrier, who was identified as Pvt. R. R.

2. That proper isolation methods being instituted, the epidemic was checked.

3. That the organism was harbored in the nasopharynx exclusively.

4. That the persistence of the carrier condition was due to the localization of the organism in the adenoid tissue.

5. That local medicinal remedies were effective in obtaining negative cultures only while they were being used, but had no value in the relief of the carrier state. On the contrary, their employment could very easily have led to a false conclusion which might have proved dangerous.

We desire to thank First Lieut. Newton Stern, M. C., for the photomicrographs of this case.

SPLENECTOMY FOLLOWING RADIUM TREATMENT FOR MYELOCYTIC LEUKEMIA.*

By H. Z. Giffin, M.D.,
Rochester, Minn.
Mayo Clinic.

The first case of splenectomy for myelocytic leukemia was reported in 1866 by Bryant.[1] His patient was in poor general condition and the spleen was very large; death occurred two and one-half hours after the operation. Bryant reported a second fatal case in 1867. The spleen in this instance was again very large and the general condition of the patient poor. Death occurred immediately after the operation.

The history of splenectomy for myelocytic leukemia is a repetition of the history of Bryant's cases and is extremely tragic. From 1866 to 1900 the operation was not infrequently performed. Approximately 86 per cent of the patients on record died within a few hours of the operation. The patients for the most part were weak, toxic, and anemic, with huge spleens and high leucocyte counts, and had insufficient vitality to respond favorably at a time when surgical treatment could be suggested and accepted. It is true that they were operated on when least could be expected. The experience of various surgeons was similar, and the conclusion naturally followed that splenectomy for myelocytic leukemia was in no sense a justifiable operation.

Bessel-Hagen,[2] in 1900, was able to collect forty-two cases of splenectomy for leukemia in which four patients temporarily recovered. Johnston,[3] in 1908, collected seven cases that had been reported between the years 1900 and 1908, with the temporary recovery of two patients. The total number of splenectomies for leukemia to the year 1908 was, therefore, forty-nine, with the temporary recovery of only six patients. It is known that of the six patients who withstood the operation, four died later. One lived as long as eight months, another lived three and one-half years. From a practical standpoint, this experience meant a very prompt mortality of at least 96 per cent. Since the appearance of Johnston's paper, the surgical treatment of myelocytic leukemia has received almost no attention. McCowan[7] (1915) reported two cases in which operation was done after preliminary treatment by means of arsenic and the *x*-ray. There was marked improvement in these patients three months after operation. The total number of cases reported in the literature to Jan. 1, 1918, is, therefore, fifty one, with eight temporary recoveries, an operative mortality of 86 per cent; four of the eight patients are known to have died later, giving a total known mortality of 93 per cent. Carstons has collected abstracts of all cases of splenectomy up to the year 1915. His article forms a complete and instructive résumé of the subject; he presents protocols of many of the published cases of splenectomy for myelocytic leukemia.

The remarkable remissions in the course of myelocytic leukemia, which can be produced by

*Presented before the Association of American Physicians, Atlantic City, N. J., May 8, 1918.

means of the exposure of radium element, or radium emanations, over the enlarged spleen, have been recently discussed by Ordway, Peabody, and the writer. The fact that the improvement following radium exposures occurred as a result of treatment over the spleen only, and not over the long bones or over any other structures, led to the inference that possibly a malfunction of the spleen might have more to do with the general condition of the patient than had been supposed. Moreover, if the spleen could be removed at a time when it was small and freely movable, and when the general condition of the patient was good, the operative mortality would doubtless be much less than it had been formerly. Again, the elimination of the spleen as a mechanical factor would remove one of the most troublesome features of the disease, and add to the patient's comfort. Naturally, in the light of the fatal former experiences, it was with considerable hesitation that splenectomy for myelocytic leukemia was resumed. The surgical treatment of leukemia has been discussed recently by W. J. Mayo and D. C. Balfour.

CASES.—In August, 1909, at the Mayo Clinic the spleen was removed in the case of a man aged 45 (Case 27,414), whose leucocyte count was 11,000, and whose differential count showed no myelocytes. In August, 1911, two years later, the leucocytes were 64,500, with 14 per cent. myelocytes. The patient died Dec. 27, 1914, five years and four months after the operation, with the symptoms of cardiorenal insufficiency. The spleen in this case weighed 2500 grams. This was evidently a leukemia of a more chronic type, as splenomegaly had been present four years preceding the operation. The total length of the history was, therefore, at least nine and one-half years. In view of the condition of the patient at the time of the operation, it is possible that life was prolonged and the patient made more comfortable by splenectomy.

Sept. 2, 1916, a spleen weighing 1100 grams was removed from a woman aged 56 years (Case 171,009). There had been no previous treatment by means of radium or the *x*-ray. The leucocyte count was 203,000 with 4.7 per cent myelocytes. Thirteen days after splenectomy the count had become reduced to 47,400 with 15.7 per cent myelocytes. The leucocytes rose to 113,800 with 36 per cent. myelocytes, 2 months after operation. The patient was in good general condition up to three hours prior to death, which occurred one year and three months after operation and was probably due to cerebral hemorrhage. The duration of the history in this case was approximately 3.5 years.

Twenty patients with myelocytic leukemia have been splenectomized at the Mayo Clinic. The two patients just discussed did not have preliminary treatment by means of radium. The remaining eighteen patients, however, were treated by means of radium exposures over the spleen prior to splenectomy. The details of this method of treatment have been discussed in a former paper.[5] The spleen in each case of this series of eighteen was very much reduced in size and the general condition of the patient was very much improved as the result of radium treatment. The eighteen patients have been operated on within the last eighteen months; the last one Jan. 21, 1918.

The operation itself has not proved difficult in cases of leukemia when the spleen was only moderately large; there have been few adhesions and but little embarrassment from hemorrhage. Postoperative complications have been absent save in one patient who died with peritonitis. Postoperative transfusion was necessary only once.

The operative mortality for the entire group of twenty cases was one death, or 5 per cent. The operative mortality in the reported cases was 86 per cent. It is clearly demonstrated, therefore, that the operative mortality need not be high with proper preliminary preparation of the patient by medical means. A mortality of 5 per cent is lower than the average for splenectomy in general. Patients in remissions with only moderately large spleens are not serious operative risks, even though they had formerly had various forms of hemorrhage.

Of the remaining nineteen patients who recovered from operation, nine have since died, from two months to one year and three months after operation (leaving out of account the early chronic case in which the patient lived five years and four months, with a total duration of history of nine years and six months). The total duration of history in eight of the nine fatal cases was from nine months to three years and six months. In seven of the eight it was more than two years.

The length of life following splenectomy seems to vary most closely, with the total duration of the disease. Eight of the nine patients dying subsequent to operation presented a duration of the disease of over two years, while six of ten living patients presented a total duration of disease of less than two years. Two living patients had a chronic type of the disease, and presented a duration of symptoms of over ten years and over six years respectively. Aside from the chronic cases, then, when splenectomy has been performed there is no reason to infer that the disease runs more than its usual course of two or three years.

Seven patients were operated on early in the disease, that is, less than six months from the time of definite onset; six of these are alive, five are in excellent, or very good condition. It is possible, though not likely, that in these early cases the results will be better than in the later ones; four of the six patients have already lived more than one year. Nothing, however, of a definite nature can be inferred from the fact that six of the seven are alive, inasmuch as the total duration of the disease in all of them is less than two years.

It is worthy of note that in two cases of a chronic type the patients are alive ten months and one year and seven months respectively after splenectomy. The total duration of disease in these two patients has been six years and ten months and ten years and seven months respectively. The spleens were large and fibrous, and the leucocyte counts were not very high. Indeed, splenectomy may prove warranted in the very chronic types of the disease, from the standpoint of the patient's comfort, even though it be ineffectual in the prolongation of life.

The ages ranged from twenty-four to fifty-six years and seemed to make no difference in mortality. In general, patients with the largest spleens at the time of operation have died first. This would probably indicate that these patients represented a more severe type of the disease. The average weight of the spleens of the patients who were first treated by radium, and who have died since splenectomy was performed, was 975.6 grams. On the other hand, those with the smallest spleens at the time of

operation have, in general, lived the longest. The average weight of the spleens of these patients was 722.5 grams. Of twelve patients who lived one year or more after splenectomy, the average weight of the spleen at the time of operation was 800 grams; in nine patients who had had a very thorough course of radium treatment it was 498.3 grams.

A period of improvement in the patient's general condition followed operation in all cases save three. This general improvement consisted of a feeling of well being, which may have been psychic, of an improvement in the appetite and the anemia, of a gain in weight, and a definite loss of the icteroid tint when it was present. The general condition in most instances was quite satisfactory before operation, so that one can not say definitely that splenectomy was the factor responsible for immediate improvement. Marked gain in weight was, however, almost a constant postoperative feature. The period of improvement was not of definite duration.

The blood, after splenectomy, showed no definite alteration, with the exception of an increase in the relative percentages of both small and large "lymphocytes." This was apparently not secondary to the fluctuation of the leucocyte count itself. Its significance is undecided and the characteristics of these mononuclear cells require further study. It is to be learned whether they are of bone marrow origin or whether splenectomy in reality stimulates the activity of lymphopoietic structures. In some instances there is a very marked decrease, temporarily in the number of myelocytes found after splenectomy.

Two patients returned for observation after operation, and on examination were found to have enormously enlarged livers, which, however, gave no discomfort. The general condition and color were quite good in one of them.

One patient (Case 180,499), who died two months after operation, and who had presented very slight enlargement of the glands, developed a remarkable glandular hypertrophy immediately after the operation, which persisted to the time of his death. The leucocyte count rose to 466,000, of which 63 per cent. were small lymphocytes and 18.7 per cent. were large lymphocytes, with only 3 per cent. myelocytes. Before operation the small lymphocytes were as low as 3 per cent. with 28.3 per cent myelocytes. The small lymphocytes rose steadily, however, after radium treatment, to the time of operation, when they were 39 per cent. with 0.3 per cent. myelocytes. Two weeks after operation the small lymphocytes rose to 61.7 per cent, and the case if then seen for the first time would doubtless have been diagnosed as a lymphatic leukemia. Examination for oxidase granules in these cells was not made. A gland examined microscopically after death showed lymphocytic hyperplasia.

Summary.—1. Twenty patients with myelocytic leukemia have been splenectomized; eighteen of them after preliminary treatment by means of radium exposures over the spleen. The spleen and the leucocyte count were, by means of radium, very much reduced and the general condition of the patients was greatly improved.

2. One patient died, an operative mortality of 5 per cent. The operative mortality of cases reported in the literature in which little or no preliminary medical treatment had been given was 86 per cent.

3. Ten of the twenty patients are living in good general condition from nine months to one year and seven months following splenectomy. However, these patients have not yet outlived the life expectancy for the disease.

4. Of seven patients operated on within six months of the time of the onset of the disease, six are alive.

5. It is probable that, at least in certain chronic types of myelocytic leukemia with fibrous spleens and relatively low leucocyte counts, splenectomy may be justifiable for the comfort of the patient.

6. A review of the cases at this time reveals no evidence that the duration of the disease is altered in any definite way by splenectomy. A detailed conception of the results following splenectomy may be obtained from an examination of Tables 1 and 2.

ANTHROPOMETRY OF SOLDIERS.

By ARTHUR MacDONALD,

WASHINGTON, D. C.

An old European military saying is, to study the enemy, know all about him, his weak and strong points, if you wish to conquer him. As we are not a military people by nature, we are prone to be too sentimental in regard to knowing the enemy. But this attitude does not help toward winning the war. Since now we are at war, we should be more military and look at the matter like soldiers.

All knowledge about soldiers, whether of our enemies, our allies, or ourselves, is power, and will help indirectly and often directly toward winning the war.

It is in this spirit, as well as with a scientific purpose, that the author is attempting to give the results of measurements of soldiers of the different countries of the world.

The difficulties of such a task are many. Since in almost all European countries military service is compulsory, each country has recorded the physical status of all its men. Anthropologists in studying their own people, and sometimes other nations, have been given access to the measurements of the soldiers, and so most of our knowledge must come from their figures, which as far as they go, are usually from official sources.

The purpose of this article is not to go too much into details, but to give such data as will furnish the general reader as well as the specialist with sufficient information to pursue such studies more in detail with the different nations. The bibliography at the end of this article will give the main sources of such work.

We are now beginning in our country for the first time on a large scale to take a physical, mental, and moral status of our men, especially young men, and it should be done as well and as thoroughly as possible. It is the hope, therefore, of the author that this effort may help toward this end, by learning what other countries and more military nations have done.

Purpose of the Measurements of Soldiers.—The measurements of soldiers are necessary as tests of efficiency and for means of identification. They also have great scientific value for purposes of race analysis and classification combined with data as to color of hair, eyes, and skin.

Many of the results of investigations of races and nations are based upon measurements of conscripts. The upper classes are not so fully represented as the peasantry, as they are better able to evade military service. It is the proletariat which reflects most the influence of race and of environment.

Practical Importance of Head Measurements.—The author has treated in another article[1] of the practical importance of head measurements, especially for identification of soldiers after death in cases where bodies are in such a state of decomposition that finger prints and other methods would be useless in determining to whom the body belonged and for whom insurance should be paid. If a tag, by mistake or with design, should be placed on a body decomposed beyond recognition and sent back to this country, insurance might be paid upon it to the family. The soldier might be missing, or a prisoner, or might have changed his name. If the head measurements (constituting the cephalic index) of the soldier in question had been made, it would in many instances help toward his identification, and thus not delay just payment of insurance to the parents, or on the other hand prevent fraudulent insurance, and thus protect the Government from loss. Also, if it were known that head measurements had been made of the soldiers, this fact alone would have great influence in preventing attempts at fraud.

It has been officially stated that the bodies of our soldiers will be exhumed after the war. This will increase the importance of identification by head measurements. In comparing the measurements of the skull, where the soft parts are decayed away, with the measurement of the head of the living person to whom the skull is supposed to belong, 5 millimeters is added to the maximum length and 7 millimeters to the maximum width. Also 2 units can be added to the cranial index of the skull for comparison with the cephalic index of the head of the living person. The time necessary to take these two head measurements is one minute. There are also additional aids to identification after death, as the teeth; also by synostoses; thus if the sagittal suture is entire, the individual is about 35 years of age or less. The condition of the skeleton also would serve as collateral evidence. Thus the calcaneum is ossified throughout at the age of 16; at 19 the epiphyses of the metatarsal bones are united to the body; at 45 the xiphoid cartilage is ankylosed to the sternum.

The head measurements, combined with the physical examination of our soldiers, would establish on a large scale the physical status of the American people, who are paying and sacrificing for this war and are entitled to such knowledge.

Scientific Importance of Head Measurements.—The measurement of the soldiers in Europe has made it possible for anthropologists, sociologists and other specialists to study their peoples, the results of which are of great benefit to the people themselves. Measurements and other data collected for military purposes become a secure basis for the investigation and understanding of important social phenomena among the people. Thus there is a long-headed type of persons, generally blonde, who have been dominant in Europe. All the leading dynasties of Europe (Ripley*) have long been recruited from its ranks. This type for years has been predominant in high political and especially military circles, which is significant, rather, than among the intellectual classes.

One specialist (Ammon) divided his conscripts into three classes: (1) The urban, those whose

1. MacDonald, Arthur: "Identification of Soldiers After Death by Head Measurements." *Boston Medical and Surgical Journal*, pages 807-809, June 13, 1918.

*See Bibliography, where the work of each authority mentioned is given.

fathers were born in the city; (2) semi-urban, those born in the city, but whose fathers were from the country, and (3) semi-rural, who, born in the country, had come to the city. Comparing these three classes with those in the country, a regular increasing long-headedness (dolicocephaly) was evident.

The shape of the head is primarily the expression of racial difference, for the head in its form seems to be uninfluenced either by food, climate, or social status, so that it is the best exponent of permanent hereditary characteristics. It appears also very probable that neither artificial selection nor environment affect the shape of the head. The other factor that might do this is chance variation. This can be determined, however, by measuring many heads so that variations above and below the average may counterbalance each other. Thus the measurement of heads on the living rather than the dead should be pursued with large numbers to assure rigid scientific results, eliminating mere chance, as may occur with small numbers. The living are much more accessible than the dead; also we know more about them than about the dead whose skulls are studied, but necessarily in limited numbers.

Pure types of head are found outside of great geographical centers of population. Africa is as uniform racially as Europe is heterogeneous. When races meet and competition is intensified, and the type best fitted to survive increases, this tends to eliminate extreme types and to produce an average type, that is, long and short heads blend, and we have medium types, that is, mesocephalics predominate.

Thus a large proportion of the residents of cities in Europe are from the country towns, at least one-half (Hansen) are of direct country descent. There is a difference in shape of head of the upper and lower classes (Ammon), that is (as already noted), the city people are more dolichocephalic than those living in the country. Lapouage of France finds, with Muffang and Collignon, that this dolichocephalic blond type with political and military prestige have a marked tendency toward living in cities.

The association of a tall person with a narrow nose is almost a law. As we go from north to south in Europe blondness decreases and brunetteness increases. According to Ripley there are three European racial types:

1. *Teutonic:* Long head and face, light hair and eyes, and tall, aquiline nose = Dolichocephalic, Germanic, Kymric, Nordic, English, French.

2. *Alpine:* Round head, broad face, light chestnut hair.

Celtic: Hazel eyes, medium (stocky) stature, variable, rather broad nose = Celtic, Slavic, Sarmatian.

3. *Mediterranean:* Long head, long face, dark hair and eyes, medium (slender) stature, broad nose: Iberian, Ligurian, Atlanto-Mediterranean.

Long head, oval face; short head, round face. The long, narrow heads, as a rule, have a smaller capacity than those in which the breadth is considerable, but the exceptions are numerous. As already noted, the shape of the head is one of the best available tests of race we have. The form of head is best designated by the cephalic index, which is the greatest breadth of the head expressed in percentage of its greatest length from forehead backward. As the head becomes broader, the cephalic index increases, if 80 or more the head is called brachycephalic; if below 75 it is named dolichocephalic, between 75 and 80 it is called mesocephalic.

Stature.—As to stature, the aristocratic classes in the cities are found to be taller than the working classes. The well-to-do are taller than the poorer classes. Also, it has been determined that brunettes are more frequent in the well-to-do classes of the cities than in the poorer city classes. Baxter found that brunettes were more resistant to disease than blondes.

Italy was one of the first countries to enter into the path which is humanitarian, patriotic, and scientific, which consists in a fundamental study of the man who is in the army with a view to knowing all his aptitudes and qualities, that he may be better trained to serve his country.

The average height of the Italian in general is 1.645 meters, that of recruits 1.624. In France (Chervin) the average height of recruits is 1.646, being 22 millimeters more than in Italy. Austria and Hungary are about the same as Italy. Venice and Tuscany have the greatest heights, while the countries in the south and the meridional provinces of the Adriatic have the lowest statures. Latitude, place of birth and economic condition from which the recruits come show differences in height.

In times of peace height is more a recognized standard for recruits; a tall man is more imposing than a short man. A man may be called tall when his height is say four inches greater than the average of his countrymen; and he may be designated short when his height is a similar number of inches below the average. We have the tall Russian and the short Japanese, which suggests the influence of race. Physiological reasons show, especially for present war methods, short men quite as well fitted for military service and probably better than tall men. It appears that the standard height of the Japanese soldier is 5 feet 3 inches, but in emergencies it is as low as 5 feet. Hence "Bantam" regiments, so-called, are desirable.

According to several older authorities, the average height of soldiers in some of the European countries was as follows:

	Centimeters	
Norwegian soldiers	169.6-169.8	(Retzius, 1902)
Danish soldiers	162.2	(Baxter)
British soldiers	169.0	(English)
" "	170.8	(Scotch)
" "	169.0	(Irish) Beddoe
French soldiers	164.9	
Russian soldiers	168.4	(Westerlund)
Italian soldiers	164.5	(Livi)
Baden soldiers	165.2	(Ammon)
Alsace-Lorraine soldiers	166.67	
Württemburg cities soldiers.	166.1	
Schleswig soldiers	169.2	(Meismer)
German Switzerland	162.9	(Kummer)
French Switzerland	164.6	(Kummer)
Italian Switzerland	163.5	(Kummer)

The average height is 8 per cent. less than the average arm-reach of men in Sweden (Retzius).

Statistics of the Measurements of Soldiers.—These measurements of soldiers, in the tables which follow, are based upon the leading authorities (see bibliography) of different European countries, especially in Sweden and Italy, where more thorough study of soldiers has been carried out.

As far as the author knows, this is the first attempt in English to present anthropometrical statistics of soldiers of different countries. The results are very variable and necessarily incomplete, and for this very reason all such data as to soldiers available should be published, so that eventually more systematic work may be done, and the data be made more useful in gaining an insight into the condition of armies, showing both the weak and strong physical characteristics of the soldiers, and thus we shall be helped to prosecute this war with maximum efficiency.

Table 1.—Cephalic Index.

Name Country.	Year.	Dolichocephalic. No.	Dolichocephalic. %	Mesocephalic. No.	Mesocephalic. %	Brachycephalic. No.	Brachycephalic. %	Total No.	Authority.
Sweden	1902	13,493	30	25,544	57	5,863	23	44,900	Retzius
Italy	1896	10,947	4	65,327	22	217,997	74	294,271	Livi
*France	1894	119	4	865	29	1,926	67	2,910	Collignon
Spain	1894	1,064	13	5,090	61	2,214	26	8,368	Oloriz
Total		12,130	4	71,282	23	222,137	73	305,519	
China Northwest Siberia	1903	79	8	372	40	491	52	942	Kozaoei
	1914	69	27	50	19	137	54	2 6	Roudenko

In Table 1 will be found the number* and per cent. of the cephalic indices of several European nations. For Sweden and Italy the numbers studied are much larger than those for the other countries and have more weight; yet the smaller numbers indicate a probability. The table shows the Swedish soldiers to be distinctly dolichocephalic (30 per cent.), as compared with Italy and France, which are only 4 per cent. dolichocephalic, but 74 and 76 per cent. brachycephalic. China and Northwest Siberia are also brachycephalic, but not in so high a degree as Italy and France.

1909	%	2	5	.....
Bulgaria	No.	3,528	9,753	.....

Table 2 shows the heights of the soldier of five countries of Europe, two in the north and three in the south. It is evident that the northern soldiers are taller than those in the south, as indicated by the mean height in the last column of the table. The great uniformity of the figures should be noted; thus Italy, France and Switzerland have the same mean height.

Table 3.—Mean Heights. Danish Committee.

Anglo-Saxons	172	Alsace-Lorraine	169	Belgium	166
Schleswig	172	Baden	169	Autsria	166
Sweden	171	Würtemburg	167	France	166
Norway	171	Switzerland	166	Italy	166
Denmark	169	Savoy	166		
Holland	169	Saxony	166		

In Table 3 is given the mean height of the soldiers of some 16 European countries, arranged in order of superiority. In general as we go south the height of the soldier decreases. The heights are in centimeters. In both tables fractions are omitted. The authorities are: For Sweden, Retzius; Italy, Livi; France, Collignon; Switzerland, Rosenfeld; Denmark, Danish Committee on Anthropology, and Bulgaria, Official Commission. (See Bibliography.)

Table 4.—Sweden. Cranial Index.

Prehistoric Periods.	Dolichocephaly. No.	Dolichocephaly. %	Mesocephaly. No.	Mesocephaly. %	Brachycephaly. No.	Brachycephaly. %	Total No.	Total %
Stone age	21	50	18	43	3	7	42	100
Bronze age	13	65	4	20	3	15	20	100
Iron age	32	63	15	29	4	8	51	100
Total	66	59	37	32	10	9	113	100
Modern times	13,493	30	25,544	57	5,863	13	44,900	100

We have constructed Table 4 so that prehistoric Sweden may be compared with modern Sweden, as to the cephalic index. The table shows that the inhabitants of Sweden, hundreds of thousands of years ago, were much more dolichocephalic than they are to-day; the percentage is almost double (59 to 30). While immigration (near the cost especially) has probably reduced the number of long-headed, the dolichocephalic type has been preserved.

That there is a distinct relation between height and cephalic index is shown in Table 5. Dolichocephaly increases as height increases in soldiers, while mesocephaly and brachycephaly decrease. These increases and decreases are quite regular and suggest a general law, that tall men are usually

long-headed (dolichocephalic) and short men round or broad-headed (brachycephalic).

Table 5.—Height and Cranial Index (Retzius).

Height in Centimeters.	Dolicho-cephalic.		Meso-cephalic.		Brachy-cephalic.		Total.
	No.	%	No.	%	No.	%	No.
159 and less	208	25	508	60	130	15	846
160-164	1,369	26	3,147	59	806	15	5,322
165-169	3,460	28	7,059	58	1,703	14	12,222
170-174	4,505	31	8,327	57	1,852	13	14,685
175-179	2,429	33	4,784	55	999	12	8,612
180-184	896	34	1,418	54	309	12	2,623
185+	206	36	301	53	63	11	570
Sum of indices and average per cent	13,493	30	25,544	57	5,863	13	44,900

Table 6.—Color of Eyes and Hair (Retzius).

Countries.	Eyes of Soldiers.			Hair of Soldiers.			
	Light.	Mixed.	Dark.	Light.	Brown	Black.	Red.
	%	%	%	%	%	%	%
Sweden	67	29	4	75	22	1	2
Baden	64	23	13	42	39	18	1
Italy	10	21	69	8	60	31	1

It will be seen from Table 6 that soldiers with light hair and light eyes decrease in Europe as we go south, letting Sweden represent north, Baden middle, and Italy south Europe. That is, blondes increase as we go north and brunets increase as we go south.

Table 7.—Height and Chest Girth in Italy.

Stature in Centimeters.	Total No. of Observations.	Circumference of Chest in Centimeters.			
		Less than 80.	80 to 85.	85 to 90.	90 and More.
Less than		1%	40%	48%	11%
160	54,537	381	21,905	26,435	5,816
160 to 165	104,632	1% 427	31% 32,454	50% 52,990	18% 18,761
165 to 170	87,372	230	22% 19,094	50% 43,469	27% 24,079
170 and more	52,764	94	12% 6,550	43% 22,870	44% 23,220
Total	299,305	1% 1,132	26% 80,033	49% 146,264	24% 71,876

In order to show the relation between the height and circumference of chest of Italian soldiers, we have formed a table based upon Livi's study of Italian recruits. The table (7) gives the figures for different heights in centimeters in connection with chest girths of certain limits. In general it will be seen that the chest girth varies with the height, that is, it is greater as the height is greater, but with some limitations.

The circumference of the chest is of great importance for the military surgeon; it is a valuable criterion of fitness for service as index of resistance to fatigue of military life.

From a careful study of Table 8 a general law is established between birth above sea level and height; that is, short men increase in number as the height of their birthplace above the sea level increases (columns 3 and 4 of table 8), and on the other hand tall men decrease as the height of their birthplace increases above the sea level (columns 5 and 6, table 8). The causes of this are complex. It is doubtless true that the deficient nutrition of men living in high altitudes has some effect on growth.

Table 8.—Sea Level and Height of Soldiers (Livi).

Distance Above Sea Level in Meters.	General Total of Observations.	Height in Centimeters.			
		Less than 160.	160 to 165.	165 to 170.	170 and More.
		15%	33%	31%	21%
0 to 50	74,659	11,330	24,754	22,929	15,646
		17%	34%	30%	18%
51 to 200	77,063	12,945	26,147	23,198	14,773
		18%	35%	30%	17%
201 to 400	72,908	13,299	25,693	21,378	12,538
		23%	37%	27%	13%
401 and more	74,725	16,970	28,042	19,889	9,824
		18%	35%	29%	18%
Total	299,355	54,544	104,636	87,394	52,781

Table 9 gives absolute numbers and percentages as to shape of forehead, nose, and face generally, and as to size of mouth, in connection with certain heights of Italian soldiers. It will be noted from careful examination of the table (83 that as to foreheads (columns 2 and 3) the high ones are more frequent in tall men and the low are more frequent in short men. The aquiline nose is also more frequent in tall men, while the flat and snub nose more often accompanies short stature (all numbers and percentages in columns 4, 5).

From columns 6 and 7 it will be seen that small mouths go more frequently with superior stature, and large mouths are more frequent in short people. The long face goes more frequently with superior height, while a projecting, flat or short face is found more frequently in short persons. Briefly, the tall soldiers are more favored with facial characteristics than the short soldiers. But as we have seen, for military purposes the short soldiers appear to have the advantage.

Table 9.—Height in Relation to Physical Characteristics of Face in Italian Soldiers (Livi, 1896).

Height in Centimeters.	Forehead.		Shape of Nose.	
	Low.	High.	Flat and Snub.	Aquiline

THE CONGRESSIONAL.

OBSERVATIONS ON HYPERTROPHY OF THE PROSTATE GLAND.

BY L. SEXTON, B.S., M.D.,
NEW ORLEANS.
TULANE UNIVERSITY.

SOME one has said that the function of the spleen, in malaria, is to enlarge. The same might be said, with equal truth, of the prostate gland in old men, as sixty-five per cent. suffer from varying degrees of enlargement. The derivation of the word, from the original Greek, is to *stand before*, and this is literally what the gland does before the urethral orifice.

Gross Anatomy.—The prostate gland is made up of two lateral and one middle lobe, surrounding the neck of the bladder, and forming the prostatic portion of the urethra. The gland is composed of muscle, glandular tissue, and stroma, all of which tissue is very susceptible to hypertrophy and growth. Some have contended that this enlargement comes mostly from the suburethral gland on the vesical side of the ejaculatory ducts—a neoplastic adenomyoma or fibromyomatous tumor, very similar to the fibroids of the uterus, originating in the walls of the sinus procularis. These tumors may be single, but are often multiple, and may be shelled out of their beds in operating very much as an onion is peeled out of its rind.

There are three clinical varieties of hypertrophy; adenomatous, fibrous, and malignant. The first type causes the greatest enlargement and mechanical obstruction to the urinary flow, which necesitates the surgical removal of the gland in the great majority of cases. The malignant type may be either epitheliomatous, carcinomatous, or scirrhous, and constitutes about ten per cent. of the cases. Occasionally prostatic tumors are pedunculated. When the enlargement is confined to the lateral lobes the obstruction to the flow of urine is greatest; the enlargement of the median lobe puts a barrier across the urethra, converting the meatus into an upward-shaped crescent. All three lobes enlarging simultaneouly push the meatus into a Y shape. If one bisects the average enlarged prostate gland, one will find that it is composed of numerous prostatic tumors and muscular tisue, that have made a capsule for themselves either out of the surrounding stroma or of the mucous membrane of the bladder wall. The normal prostate, in the average adult at twenty-one years of age, should weigh a little less than an ounce. The average weight of tumors removed is about three ounces, while in some cases they have weighed as much as twelve ounces. The tendency of the tumor is to grow upwards and backwards under the vesical mucous membrane, causing a considerable lengthening of the urethra, so much so that the length (of eight inches) of the normal urethra may be increased to sixteen inches.

Causes.—The causes of enlarged prostate are sexual excitement, age, horse-back and other rough riding, infections (gonococci), exposure to cold and damp, stone in the bladder, and other irritations and pathological developments of tumors in the prostate gland from constant sexual congestion. While the enlarged prostate is mostly confined to men passed fifty years of age, young men, who are high livers and of bibulous habits, constantly infecting themselves with gonorrhea, may also have their prostates enlarged. Occasional acute causes are abscesses and cystitis.

Symptoms.—The growth of the tumor up and under the mucous membrane of the bladder produces a pouch, which contains residual urine, and in many cases is the seat of a beginning cystitis. The straining effort to get rid of the residual urine causes the bladder muscles to thicken at first, but afterwards atrophy of these muscles may occur as a result of the continuous dilatation of the bladder. Incontinence of urine may also be expected after the bladder has been dilated to the utmost for a long period. This residual urine undergoes ammoniacal decomposition, which irritates the bladder wall, causing a constant desire to pass urine, especially at night,. while in the recumbent position. Sleep is interfered with, and more than this—the back pressure from the distended bladder and ureters causes a reverse current and dilatation in the ureters, carrying infection and congesting the kidneys, and sometimes producing pyelitis.

Phosphatic calculi may form and become encysted in the bladder or prostatic wall and produce no particular trouble, beyond adding to the vesical irritability, but if the stone remains loose in the blader, it adds more obstruction to the outflow of urine. The bladder wall, as a result of its distention, may lose all its propulsive power, causing the urine to be voided very slowly or to dribble away. If chronic nephritis results from the infection, the amount of urine is increased, and the necessity of voiding it more frequently seems to add insult to injury. The stream of urine may not be smaller than normal, but there is less force to propel it. The residual urine is alkaline from phosphates; and muco-pus, if it extends up to the kidney, is a common cause of pyelitis or uremia. Overindulgence in drink, abuse of the sexual function, and exposure to cold and damp may bring about a crisis in which the urine is suddenly stopped. Straining opposes, rather than helps, the expulsive effort. We cannot always determine the amount of obstruction by the size of the prostate. Obstruction of the rectum and constant straining, while urinating, causes hemorrhoids; and very large prostates may so press upon the rectum as to retard its function.

Diagnosis.—A patient having to void his urine six times, or more, during the night, and as often during the day, if passed the age of fifty, comes either in the nephritis or enlarged prostate class. This frequency may not be so noticeable during the day, due, of course, to the upright position. The enlarged prostate can always be felt by a thorough digital examination of the rectum. Dullness on percussion over the pubis, caused by a distended bladder, indicates prostatic obstruction. (Enlarged prostates are often responsible for a *vicious circle* established in old men and evidenced by priapism, sexual perversion, and gross indecency.) Relaxing the sphincter is necessarily slow at the beginning of urination; acute retention makes catheterization imperative. Cystitis and renal symptoms soon follow in close succession. The last urine squeezed out of the bladder usually contains pus and blood, also albumin from the prostatic fluid with which it is mixed. Casts will also be found if the kidneys are involved. A cystoscope occasionally aids in diagnosis.

When urinary expulsion is impossible, and a catheter life becomes necessary, the patient, before being permitted to catheterize himself, should be carefully instructed in asepsis and the use of a web or rubber catheter. The gum or web catheter is preferable for the patient, but the doctor usually prefers the metallic instrument, as it serves as a long finger to help him diagnose a stone in the bladder, the amount and extent of obstruction, together with increased length of the urethra In order to enter the bladder, the doctor very frequently needs a variety of catheters, bent at different angles at the end (coudé), of unusual length, and small in size, in order to relieve the distended bladder, and, even then, it sometimes becomes necessary, in emergency cases, to use a suprapubic trocar and cannula With the best instructions, in the hands of the patient, the use of the catheter very frequently leads to a regretable infection. The chill and fever which may follow the introduction of the catheter are due to the absorption of the bacteria if the mucous membrane of the bladder is traumatized. A hypodermic of atropine and morphine is the prophylactic remedy for urethral chill. However, we have known of many patients who have been carefully instructed in the methods of keeping the instruments sterile and properly lubricated, living comfortable lives for many years by this palliative treatment alone The use of the catheter should be limited to the preparation of the patient for an operation, and for the immediate relief of a distended bladder, and should not be recommended as a curative measure at all. As the doctor and nurse cannot always be present when it becomes necessary to void, it is important that the patient be carefully instructed in asepsis and lubrication of instruments, as just mentioned. In evacuating the bladder (in cases of enlarged prostate) the long curved silver catheter is preferable, but the stem has to be long and pressed far down between the thighs before the urine will flow, on account of the increased length of the urethra If a patient can pass eight ounces of urine without a catheter, every four hours, his kidneys and blader may be considered functioning very well.

Treatment.—This is prophylactic, palliative (catheter and suprapubic drainage), and radical, or removal of the gland. The usual internal remedies are five grains each of boric acid, salol,. and hexamethylenamine. Rest, which is very important in all bladder affections,. is classed among the best palliative measures in the treatment of hypertrophied prostates The catheter treatment is recommended only for the age-infirm and diseased, who cannot undergo an operation but must have their bladders emptied. Patients requiring a prostatectomy are usually advanced in years, with a trinity of diseases—cardio-vascular-renal; hence, are bad subjects for any operative procedure. Residual urine, diseased bladder wall infection and resultant cystitis add other serious obstacles to the operation. Septic catheter, stone in the bladder, pyelitis, and other complications, all taken together, do not present a very promising picture for recovery after operation The percontra of these unfavorable conditions, which weigh in the balance on the operative side, is that operations drain the infected bladder, relieve the pain and back pressure from the ureters and kidneys, and get rid of the residual urine, pus, and stone, if present. Bladder irrigation can be done effectually, and all sepsis washed away, through a large drainage tube; and the constant risk of infection through a septic catheter is eliminated. We know of no desperate condition in surgery, for which more prompt relief can be obtained, than is afforded by a suprapubic drainage of these foul bladders.

As a preliminary to any operation, rest in bed must be enjoined, and a diet of milk, cereals, vegetables, and fruit instituted; all meats, condiments, salt, coffee, tea, and alcohol should be avoided, the same as in kidney diseases. Many patients eighty years old have been operated upon successfully, and days of prolonged pain and inconvenience relieved, with many happy years added to their lives. The operative mortality, even in these old cases, should not exceed four per cent. in the hands of competent surgeons. Irrigating the bladder with two ounces of

one to five thousand nitrate of silver solution, introduced into the empty bladder and allowed to remain, though painful, often works wonders in these cases; but this should be followed by daily injections with two per cent. solution of some of the organic silver salts, or with warm two per cent. boric acid solution, until the bladder is relatively clean, before any operation is undertaken. Remember that ether, shock of operation, or absorption of bacteria may unbalance diseased kidneys which are functioning sufficiently well to keep elimination ahead of the production of waste. Do not allow yourself to be hurried into operating upon these cases until they are thoroughly prepared, as only fools rush in where experienced surgeons hesitate. It is usually preferable to make two stages of the operation rather than to attempt to do too much at one sitting on these bad surgical subjects.

Operation.—After antiseptically preparing the patient, an incision about two or three inches long is made in the median line just above the symphysis pubis, being careful not to open the peritoneal cavity. After the incision is made through the fat, the bladder wall can be seen in the space of Retzius; if the peritoneum encroaches upon the upper bladder wall, it should be held out of danger with a retractor. Two silk sutures are inserted, on either side, into the bladder to support its wall in position while the viscus is opened and drainage tubes put in. If the bladder is not to be opened at the first operation, the wound is packed with plain or iodoform gauze, and left for from twenty-four to forty-eight hours, when, after local analgesia, it is opened and a large drainage tube is inserted through this opening and held in place by sutures. Through this tube, or tubes, the bladder may be irrigated with hot boric acid solution, or sterile water, leaving the removal of the prostate gland to a later period, when the bladder is free from sepsis and the kidneys are relieved of congestion. The condition of the patient is much more favorable for the second stage of the operation. To raise up the peritoneal membrane in this operation, the bladder should be distended either with air or with twelve ounces of boric acid solution, or by inserting a Peterson bag into the rectum and moderately distending it. The Trendelenburg position also assists in raising the peritoneum. The enlarged prostate can usually be shelled out by the finger, breaking through the mucous membrane at the meatus, following the line of cleavage with least resistance. For the removal of the gland, the finger serves a better purpose than cutting or gouging instruments, which increase the risk of hemorrhage. A silver catheter should be held in the urethra by an assistant, as this enables the surgeon to determine the mouth of the urethra, which should be enlarged by the finger tip, while determining if the prostatic portion is yet intact. Among the chief dangers of operation at this period are shock and hemorrhage: the former should be blocked by a preliminary dose of morphine and atropine, and hemorrhage checked by direct pressure, a suture, or packing with gauze. The end of the gauze should protrude through the external opening, and may be removed whenever we are positive the hemorrhage is checked. On the other hand, the introduction of the finger into the rectum, and the application of direct pressure with gauze in a sponge holder, will usually prevent the necessity of using either sutures, packing or styptics, which might irritate the bladder. Cuts into the prostate with Bottini's galvanocautery, double castration, vasectomy, and ligating the internal iliacs to starve the growth of the gland, are now very rarely resorted to. Some surgeons prefer a horseshoe perineal incision to remove small and fibrous prostates, on account of leaving the drainage in the most dependent portion of the wound, at the same time being able to use instruments in removing the gland.

In operating upon the glands, as suggested above, we have had successes, and but few failures to relieve these old men.

Medical Building, New Orleans, La.

PURPURA RHEUMATICA.

By LEWIS J. FRIEDMAN, M.D.,

NEW YORK.

ALTHOUGH the old view that simple purpura, purpura rheumatica, and purpura hemorrhagica are distinct diseases has been largely abandoned, it is necessary for the purpose of description to retain these terms. According to Osler's definition purpura rheumatica (peliosis rheumatica of Schönlein) is in reality a simple purpura with arthritic manifestations.

The clinical classification of acute and chronic is also applicable to purpura, though the latter condition is not so frequently seen. The more appropriate term for chronic purpura is chronic recurrent, because of the intermittency of the symptoms. The case which I shall describe below belongs to the latter classification and it is on account of its infrequency that I am reporting it.

Etiology: Johnson[1] claims to have isolated diplococci from lesions in cases of purpura rheumatica. A. Ernst[2] reported epidemic purpura in barracks and other over-populated confines. Cowel,[3] on the other hand, failed to produce purpura experimentally. Stephen MacKenzie found a history of rheumatism in 61 out of 200 cases of purpura. In my case of chronic recurrent purpura I could elicit no history of rheumatism or of an infectious process existing prior to the first appearance of the symptoms. It is possible that a disturbance in metabolism may have been responsible for the original attack and the subsequent recurrences. Magnus-Levy[4] found serious disturbances in metabolism in a case of purpura hemorrhagica.

CASE.—L. E., male, aged 20, single, wood carver by trade. Father died from pneumonia, mother and a sister living and are well. He had measles, chickenpox, and whooping cough during childhood. Venereal history, negative. Has had an occasional epistaxis during the past few years, of a very mild character. Has been in perfect health otherwise, until April, 1914, when he first noticed a few small purpuric spots about 3 to 10 mm. in diameter, mostly on the lower limbs, accompanied by pain and slight swelling of the knees. The attack was not severe enough to incapacitate him from work. This condition lasted about a week, and then subsided to recur two or three weeks later. The purpuric eruption in the subsequent attacks appeared in different areas, and other joints, such as the wrists, metacarpal, phalangeal, etc., would become slightly swollen and tender. Another condition brought out on

questioning was that the least amount of trauma to any part of the body produced a purpuric eruption.

He appeared to be a youth of average size and weight; mucosa normal; nasal, oral, and aural cavities showing no defects. Heart and lungs negative. He had a few purpuric spots on the arms, forearms, buttocks, and thighs. Some of the extravasations were in the process of absorption. His right wrist and left knee were slightly swollen and painful on motion. On testing the coagulability of the blood by Millian's test, I found it coagulated in 12 min. The urine was negative.

The treatment which I thought of based upon Johnson's infection theory was autohemotherapy. The technique employed was the drawing of 5 mils of blood from the median basilic vein and then injecting it intramuscularly. After I had tried this method three times in the course of twelve days, the patient objected to further injections. There was to my mind a visible improvement, though it was too soon to state definitely as to the value of this kind of therapy. I have subsequently tried the usual list of preparations recommended for this affection by Osler and Forschheimer, with only temporary relief.

Calcium lactate is less irritating to the alimentary tract than the chloride and therefore preferable. Arsenic can be given as Fowler's solution, but in order that its full therapeutic effect be obtained, it should be given to toleration. Sodium cacodylate can be given intramuscularly in 3-grain doses for several days in succession, omitting three days, recommencing, and so on.

After several months of treatment and intervals of quiescence of symptoms the patient discontinued seeking relief, and I have eventually lost sight of him.

Since reporting this case I read that J. A. Sincord[5] noticed good results from homohemotherapy, which consisted of subcutaneous injections of 80 to 120 mils of blood taken from a healthy individual.

Until the etiology of purpura is well understood it is difficult to treat this affection, except empirically as heretofore, hoping for an amelioration of the symptoms.

Medicolegal Notes.

Insufficient Evidence of Malpractice.—In an action by a patient against a physician for a tort to the person the jury gave a verdict for both actual and punitive damages. The physician appealed. The appellate court said: "The alleged tort arose out of the treatment of the plaintiff by the defendant for piles. The charge is that the treatment was both negligent and wilful. We have considered the testimony, and there is no room to infer from it that the defendant was either negligent or wilful in what he did. The only negligent act suggested by the plaintiff's counsel at the bar was the persistent treatment of the patient, notwithstanding the pain which the treatment gave the patient. The defendant offered no testimony to prove that piles could be treated without pain. Negligence is not a reasonable inference from the bare fact that pain accompanied treatment.

"There was no testimony tending to prove that the compound injected, or that the instrument used for the injection were unfit. On the other hand, one of the plaintiff's expert witnesses testified that he 'had heard of treatment by injection, and that some reputable physicians use the same now.' Counsel for the appellant was unable to suggest at the bar any act or any utterance of the defendant which pointed to his wilfulness, and the testimony shows none such. The court ought to have directed a nonsuit, and must yet do so.

"The court furthermore excluded all testimony to show specific instances in which other persons had been benefited by the treatment which was administered to the plaintiff. The complaint alleged 'that the defendant is commonly called and designated as a quack and ar impostor, and that he is unskilled and unlearned in his profession, and was and is wholly incapable of relieving or curing piles in and by the manner of treatment which he applied to the plaintiff, and that the defendant well knew such fact.' The issue then which the plaintiff tendered by his pleading was that the remedy was specious, and the defendant knew the fact. If it be true that the defendant applied the same remedy to others than the plaintiff, which others had a like affliction, and with helpful results, that would tend to disprove the plaintiff's allegation. The testimony was competent."

The judgment was reversed, with directions to enter a nonsuit for the defendant.—Thomas v. Register, South Carolina Supreme Court, 96 S. E. 517.

Practising Without License.—In a prosecution against a chiropractor for practising medicine without a license, as required by the Missouri statute, it was held that requested instruction to acquit, if the defendant treated a patient at her request and without reference to her ailments was properly refused, in view of evidence that the patient knew the object of the treatment was to give her such relief as it might afford. The court said that if such a mental attitude on the part of the defendant could be tortured into a defense to the charge of treating the sick and infirm without complying with the law regulating the practice of medicine and surgery, then the law would be practically a nullity. The court quoted from State v. Smith, 233 Mo. 252, 135 S. W. 466, as follows: "In actual practice the chiropractor makes no physical examination outside of the spinal column. He does not feel the pulse, take the temperature, prescribe any diet, or use any instruments. He simply examines the spinal column, determines whether or not a subluxation, as he calls it, exists, and if he finds it, adjusts the same. . . . The Legislature thought, perhaps, that this act (that of 1901) was necessary to protect credulous sick people from injury at the hands of charlatans and quacks, with their specious promises of a sure cure without drugs; or, it may have been thought necessary to forbid harmless practices in order to insure protection against those that are dangerous and hurtful. Sick people sometimes grow desperate in their search for a cure, or their judgment becomes weakened, so that they fall an easy prey to the ingenious and varied devices of the pretended healer. We know that some people are prone to give more weight to a skillfully worded advertisement than to the advice of a competent physician. The Legislature, no doubt, thought that, in view of all these considerations, the welfare of the people required the sweeping law of 1901."—State v. Fenter (Mo.), 204 S. W. 733.

Expert Testimony—Range of Bullet.—In a prosecution for murder a surgeon and an expert, who attended the deceased from shortly after the shooting until his death, and who testified as to the wound, the range of the bullet, and the place of entry, was permitted to testify as an expert that a bullet, if fired into a man lying on a fence, could have taken the range taken by the bullet that killed the deceased.—Houston v. State, Texas Court of Criminal Appeals, 204 S. W. 1007.

Prescriptions of Intoxicants.—In a prosecution of a physician for prescribing liquor without good reason to believe the patient to be actually sick or that liquor was required for medicine, the evidence of five other prescriptions each for one quart of whisky given to such patient at the same time was held competent by the Washington Supreme Court on the question of the physician's good faith; the prescriptions obviously calling for more liquor than the patient needed if taken as directed. They were not incompetent as proof of independent crimes; the gravamen of the offence being the faith in which the prescription was given, and not the act of prescribing. Such evidence was held sufficient to sustain a conviction.—State v. Raub, 173 Pac. 1094.

Military Medicine.

Period of Latency of Shock.—Baruch, in the *Archives Médicales Belges* for October studies the phenomena of shock from this special viewpoint. Initial shock is extremely rare or in other words nearly all traumatic shock is delayed and has a period of latency, which may be two or three or more hours and is of great interest. Unfortunately the complexity of the phenomena in this interval is very great. Quénu would restrict the term shock to what transpires immediately after a wound. If there is an inhibition of the nervous system due to the injury it cannot be that it only manifests itself 3, 4 or 5 hours later. If by dilatation of a fissured anus we can produce an arrest of the respiratory centers this arrest occurs at once and not after an interval of latency. When the testicle is crushed a disturbance of arterial tension occurs at once and not hours afterward. The author insists, however, that the wound can produce a loss of nerve tonus, the effects of which are not at once manifest. Shock seems to represent an inactivity of the nervous system which affects especially the vegetative centers—medulla, cord and ganglia—and incidentally the vagus nerve. An analogue to shock may be seen in the oculocardiac reflex. The varying behavior of the latter also suggests varying predisposition to shock. Many components enter into shock, such as injury, loss of blood, infection, anesthesia, etc., which are of course absent in this reflex. In both the latter and in shock-states a certain laboratory test gives the same result—the faradization of a centripetal nerve causes a rough outline of the vascular reaction of deep shock. The milder the shock the more marked is the reaction. While shock d'emblée occurs after wounds the ordinary sequence is a retardation due to a cellular inhibition of the cells of the vegetative centers.

But whatever the nature of shock the clinical picture is dominated by two factors, hemorrhage and infection. What then is the relation of these to the period of latency? Both of these conditions profoundly modify the disease picture. In regard to blood pressure it is known that the greatest rises—40, 50, 60—mean death, while if the return toward the normal is less marked—20, 30—the prognosis is excellent. This teaches that the subject is not one of blood pressure alone. The response to cardiac stimulants may for the same reason be misleading.

Certain early deaths may be explained by acute anemia alone without any component of shock, and in general the status post-hemorrhagicus differs radically from shock yet may closely resemble it. In regard to infection it does not of course, develop at once but several hours later. Death in from 3 to 6 hours must be set down to shock. Infection then does not tend greatly to complicate the latent period of shock.

Intravenous Injections of Camphor in Shock.—In the October 5 number of *Le Progrès Médical* there are two articles on this subject, one clinical, while the other is concerned with the behavior of the blood pressure in this form of treatment. The paper by Ferrari refers to the variety of substances tested for this purpose. Some of them, including camphor, received experimental laboratory tryouts. Since camphor is injected in oil, a special problem is involved which merges into that of the lipovaccines. The pioneer work along these lines was reported by Le Moignic before the *Académie des Sciences* last February. Soon after this period the author began to use the camphor injections on the battlefield. It was at the time of the great German offensive and the afflux of wounded was so great that there was no time for systematic studies. The author, however, is able to present six cases which could be followed up. The first was in a man with multiple gunshot fractures, who was badly shocked. The pulse was 138 and thready. The blood pressure was not taken. The treatment consisted of heat, alcoholized drinks, and intravenous injection of camphorated oil. Under this management the improvement was such that it was decided to operate. The intervention, which included primary resection of the left knee, several removals of bone fragments and the laying open of a seton wound, lasted 65 minutes. The patient was now once more in shock with pulse of 140 and thready, and received more camphor, with the other shock treatment. On the following day he was better but extremely weak and a third injection was administered. After this he was well .enough to be evacuated to the interior. The other five cases were similar in character and result. No other medicament was used in these cases, but one received a blood transfusion. The author who saw no untoward result, nevertheless hesitates to recommend the remedy for routine usage because the material is so limited. No one knows what a fourth injection might do or what the limit of tolerance is. One injection before and one after the operation with a third if the response is incomplete are good as far as they go. There should be a favorable reaction after half an hour. The dread of pulmonary oil embolism seems unwarranted. As adjuvants the toxic factor, which Quénu has proved to exist, must be disposed of by operation, while transfusion may be demanded as a result of loss of blood.

In the other paper by Jeanneney, blood pressure finds before and after camphor injections are given on four soldiers. The shock in these cases seems to have been entirely postoperative. The camphor, used as a last resort, gave wonderful results in reanimation and the blood pressure curves show that the heart is given a notable push. A slight fall sometimes seen after injection may be due to capillary embolism.

Vegetable Ration of the British Army in India and the Far East.—During the first Burmese war, British troops suffered considerably from scurvy. In cantonments, in after years, garden allotments were sanctioned, and the soldier was encouraged to cultivate vegetables. Experience in the Mesopotamia campaign early pointed to the necessity of vegetable diet, and resulted in the despatch to that area, in March, 1917, by the Madras War Fund of a body of men 256 strong, known as the Madras Gardeners' Corps. The corps largely extended a garden already in existence at Sheik Saad; they made a new garden at Bagdad, and

according to a report published by the Madras *Mail* last spring, they "helped to start numerous gardens all over the country, by supplying hundreds of packets of seeds and scores of baskets of seedlings to various units." At Bagdad the estimated output of vegetables was 413,820 lb., at Sheik Saad, 701,224 lb. The general verdict is that the soil of Mesopotamia possesses extraordinary fertility. A body specially organized to secure cultivation of vegetables is an innovation in the modern hygiene of armies that is likely to be held in mind in future campaigns. Nor in cantonments in India will the nature of vegetables used by soldiers be in future so greatly subject to local meteorological and communication difficulties. The following scale for British troops in India has recently been ordered: Potatoes, 035.6; fresh vegetables other than onions, 03.8. The scale will be varied by the issue of substitutes as circumstances may permit. When substitutes are issued the following scale of equivalents will apply: 1 lb. potatoes, 1½ lb. onions, or 2 lb. fresh vegetables other than onions, or 4 oz. unsplit dhall germinated. The direction to employ germinated dhall would seem to be the outcome of recent work by Miss Chick, Lister Institute, in connection with the recognition of vitamines. It may be here remarked that although the consumption of legumes in a germinating condition is not followed by Indians, it is an established custom with the Burmese; beans in a sprouting condition being specially prepared and sold for food purposes in the bazaars.—*Tropical Diseases Bulletin, October* 15, 1918.

Health of American Army Excellent.—Major-General William C. Gorgas, in his annual report as surgeon general, made public on December 6, states that the health of the American Army both at home and abroad has been excellent, and the mortality rate from disease probably lower than in any similar body of troops in the history of warfare. Complete statistics of deaths in army camps are not included in the report, which covers only the fiscal year to June 30, 1918. In 1917 total deaths from disease were 2,984, and the death rate per thousand 6.3; the seven-year average has been 4.9. General Gorgas points out that had the morbidity of typhoid fever been the same as in 1898, there would have been 1,400 deaths from that disease alone, whereas there were only 23. Measles is placed at the head of diseases causing death, although the records show that 65 per cent. of these deaths were due to resultant pneumonia.

Distribution of Wounded Soldiers.—The War Department has announced plans under which all wounded men returning from France will go to hospitals within three hundred miles of the homes of their nearest relatives. To this end, base hospitals at training camps have been turned over to the surgeon-general providing seventy-five hospitals with facilities to care for 104,231 men. Fifty thousand men are expected to be sent to these institutions within the next four months. The seventy-five hospitals do not include those at the ports of debarkation, New York and Newport News. At these ports the wounded will be received on their arrival from France in fifteen institutions now ready for them, with a bed capacity of 22,068. From the ports the men will be taken in specially fitted trains to one of the sixteen localized hospital groups, where assignments will be made in such a way that wounded men will go back to the region from which they entered the service. It is estimated that increased hospital facilities costing $26,000,000, and providing 13,000 beds, will be necessary to make full provision for the returning wounded. Assistant Surgeon General Stimson of the Public Health Service has asked the House Buildings Committee for an initial appropriation of $10,000,000 to provide the first 5,000 beds. New hospitals are planned at Norfolk and Seattle, and at sites yet to be selected in the Massachusetts Berkshire Hills and in North Carolina. Additions also are planned to the marine hospitals at Boston, Chicago, Cleveland, Detroit, Evansville, Louisville, New Orleans, San Francisco, St. Louis and Wilmington, N. C., and at the Fort Stanton (N. M.) Sanitarium. The use of the training-camp facilities will make possible the return to their owners immediately of the following properties which were to have been converted into general hospitals: New Field Museum, Chicago; Exposition Park, Rochester, N. Y.; State School for the Deaf, Columbus, Ohio; Richman Bros. Building, Cleveland, Ohio; Deutsches Turnverein, Cleveland, Ohio; High School, Cincinnati, Ohio; City Sanitarium, St. Louis, Mo.; Ford Building, Milwaukee, Wis.; Brockman Stores, Milwaukee, Wis.; Badger State Sales Company, Milwaukee; Woodstock Apartment, Milwaukee; State School for the Blind, Nashville, Tenn.; Sophie Newcomb School and Tulane University Buildings, New Orleans; Byberry Farms, Philadelphia; Elks Hospital, New Orleans; Sea View Hospital, New York; Ford Building, Des Moines; St. Catherine's Home, Des Moines; North Brother Island Hospital, New York; Catholic Orphan Society, New York.

Relief Fund for Italian Blind Soldiers.—The Permanent Relief War Fund for Soldiers and Sailors of the Allies, having its office at 590 Fifth Avenue, New York, has cabled 100,000 lire to the Italian Ministry of Foreign Affairs. It was requested that this donation be handed to King Victor Emanuel for distribution as he thought best among his sightless subjects who have been victims of the war.

Red Cross Work in Palestine.—A report recently received from Dr. W. S. Dodd, working at Mejdel, near Jerusalem, records some of the difficulties that confront the workers in that locality, and described some of the results accomplished. With two capable English trained nurses and three native helpers, Dr. Dodd, in his hospital housed under tents, performed 252 operations in seven weeks, besides giving medical examinations, treatment, and counsel to hundreds of destitute inhabitants and refugees. While they had all classes of cases in medicine and surgery, far the larger proportion of their patients were eye cases—222 of the 252 operations were upon the eyes. Trachoma and its consequences accounted for most of the eye cases seen in this land. He found that even under the difficulties of the situation he was able to save a number of eyes from partial or total blindness. The report refers to unspeakable

conditions due to lice and maggots, which are a daily terror; many wounds and injuries come filled with maggots.

Red Cross Plans Permanent Service.—In a statement recently issued to the 3,854 chapters and the 22,000,000 members of the American Red Cross, Henry P. Davison outlines the future plans whereby the organization built up during the war will devote itself to relief work throughout the world. Study is being given not only to problems of international relief, but to plans for this country for enlarged home service, the promotion of public health education, development of nursing, the care and prevention of accidents, and other correlated lines which may contribute to the health and happiness of men, women, and children. The international relief work will be done in cooperation with the National Red Cross and other relief agencies of other nations. The task of fighting tuberculosis, promoting child welfare, and caring for refugees, with which the American Red Cross has concerned itself in France, Belgium, and Italy, will at an early date be assumed by the governments, the Red Cross organizations, and the relief societies of those countries. From a financial standpoint the American Red Cross announces that it is in a thriving condition.

Health of the Navy.—Surgeon General Braisted in his annual report, presented on December 9, says that the health of the navy during the past year has been excellent, and he attributes this largely to the increasing appreciation by commanding officers of the rules of hygiene and sanitation. Compared with an annual death rate of 2.7 a thousand for the ten preceding years, the rate rose during the first quarter of this year to 8.9 a thousand a year. This, Dr. Braisted finds, was "due to the unfortunate and unavoidable combination of circumstances brought about by the rapid expansion of the navy and the unusual weather conditions in the first quarter of the year. The death rate for the second quarter was low, 3.3, a figure closely approaching the average for peace times." During the year 193 men were drowned, 30 died from exposure, and 47 were killed by gunshot wounds. The war has served, Dr. Braisted says, to clear the reputations of the men of the army and navy of the impression in the public mind that venereal diseases were more prevalent in the service than outside.

Deaths in the Service.—Captain Halstead Robert White, M. C., U. S. Army, of Columbus, Ohio, a graduate of the Ohio State University, Columbus, in 1910, died at Base Hospital No. 14, Fort Oglethorpe, Ga., from pneumonia following influenza, on October 17, aged 42 years. He was a member of the American Academy of Ophthalmology and Oto-Laryngology, and formerly instructor in physiology and pathology of the eye in his alma mater.

Major Shadworth Oldham Beasley, M. C., U. S. Army, of San Francisco, Cal., is reported to have been killed while on duty with the American Expeditionary Forces in France, on October 14. Major Beasley was 42 years of age, a graduate of Cooper Medical College, San Francisco, in 1897, assistant clinical professor of obstetrics and gynecology in Leland Stanford Junior University, and a major of volunteers during the war with Spain, on service in the Philippine Islands.

Lieut. Samuel Lewis, M. C., U. S. Army, of Brooklyn, N. Y., a graduate of the Long Island College Hospital in 1917, aged 22 years, is reported as having been killed while in service with the British Expeditionary Forces in France on August 28.

Captain George Edward Farr, M. C., U. S. Army, of Shelbyville, Mo., a graduate of the University Medical College of Kansas City, Mo., in 1906, died from pneumonia at Brownsville, Texas, while on duty on the Mexican border, October 30, aged 39.

Lieut. Arthur McQuaid, M. C., U. S. Army, of Chicago, a graduate of Loyola University, Chicago, in 1915, on duty at British war hospitals in England from October, 1917, to July, 1918, and since that time serving with the British Expeditionary Forces in France, is reported to have been killed in action on October 15, at the age of 28 years.

Lieut. Harry Shaler Matcley, M. C., U. S. Army, a graduate of the University of Syracuse in 1911, aged 32 years, formerly anesthetist to the Hospital for Ruptured and Crippled, New York, died while on duty at Camp Eustis, Va., November 18.

Captain Joseph Dudenhofer, M. C., U. S. Army, of Erie, Pa., a graduate of Jefferson Medical College in 1911, aged 30 years, was killed in action on September 17, with the American Expeditionary Forces in France.

Lieut. Malcolm Cunningham, M. C., U. S. Army of Chicago, a graduate of the Chicago College of Medicine and Surgery in 1917, aged 25 years, died from pneumonia following influenza, while on duty with the Seventy-sixth Spruce Squadron, Astoria, Ore., on October 8.

Lieut. Grover Carlisle Price, M. C. U. S. Army, of Judson, Ind., died from bronchial pneumonia while on duty with the American Expeditionary Forces in France, on October 30, aged 30 years.

Lieut. Timothy Gibson Sellew, M. C., U. S. Army, of Marietta, Ohio, a graduate of the Medical College of Ohio in 1901, died from heart disease while on duty at Camp Grant, Rockford, on October 20, aged 43 years.

Lieut. Clinton Virgil Reed, M. C., U. S. Army, of Three Forks, Mont., a graduate of Rush Medical College in 1914, died of pneumonia following influenza, recently, while on duty with a medical unit in England, at the age of 29 years.

Lieut. Millard Cressy Clark, M. C., U. S. Army, of Bethlehem, N. H., a graduate of Tufts Medical College in 1917, died from bronchopneumonia at Camp Gordon, Ga., on September 29, aged 25 years.

Lieut. Leslie James Phillips, M. C., U. S. Army, of Weyerhauser, Wis., a graduate of Queens University, Kingston, Ont., is reported to have died recently in France from pneumonia, at the age of 30 years.

Lieut. Alfred Johnson, M. C., U. S. Army, of Clyde, Kan., a graduate of the St. Louis College of Physicians and Surgeons, 1907, on duty at San Francisco, died at his home, of influenza, on November 6, aged 39 years.

Lieut. Albert Frederick Ostwald, M. C., U. S. Army, of Buffalo, N. Y., a graduate of the University of Buffalo in 1911, died at his home on November 18, aged 35 years.

Lieut. Arthur Hastings Wheeler, M. C., U. S. Army, of Albany, N. Y., a graduate of the Albany Medical College in 1912, died in California on October 26, aged 30 years.

MEDICAL RECORD.

New York, December 14, 1918.

CONCERNING FELLOWSHIP WITH GERMAN PHYSICIANS.

THE war will probably soon be over, unless the Germans by some new act of treachery force the civilized nations to go in and beat them to the ground. When it is over the question will come up as to what we are going to do with the German medical men. Are we going to admit them to fellowship again as though nothing had happened? That is unthinkable, for the physicians of Germany have vied with the other professional classes and university men in spewing out their hatred of the decent nations and in gloating over the barbarism and unspeakable cruelty of their ruling classes and the army. We have been accustomed to think that the collective soul of the medical profession is farther along than those of most other professions and avocations—more altruistic and more humane. But we have left out of our thinking the brutalizing effect of Teutonic environment. We have forgotten our student days when we shuddered at the inhumanity displayed in their clinics by the leaders of the medical profession in Germany—the brutal disregard of the feelings, mental and physical, of the patients driven by their sufferings to seek relief even at a university clinic.

The German physicians are, just as we should have expected to find them, much of the same material as their military masters. When the German brutes were bombing hospitals and torpedoing hospital ships, did any German physician raise his voice in protest? Not one, or if there was one his feeble note failed to carry across the water. The German medical journals not only published no protests but even expressed approval in some cases of the vilest atrocities. In the *Deutsche medizinische Wochenschrift*, the leading German medical weekly, for example, the editor, Dr. J. Schwalbe, wrote exultingly of the work of the submarine pirates in sinking the *Lusitania*, and sneered at President Wilson's mild remonstrances against a repetition of the crime. The editor of the *Münchener medizinische Wochenschrift* was also well pleased with this infamy. But the German doctors were not content with a passive approval of their country's disgrace, they were actively inhuman—looters and worse. The reports of their crimes are piling up, especially now that the prisoners are getting back from the hells of German cruelty and are relating their sufferings—tales of desertion of German doctors when epidemic disease appeared in the prison camps, of neglect in many cases to care for the prisoners' wounds, of incredible brutality in other instances in the treatment of the sick and wounded, of jeering at the sufferings of English officers weakened by loss of blood, blows, and starvation, of the theft of instruments from Belgian surgeons in whose homes they were billetted—but the list is too long. There is material for a large black book of medical crimes, less coarse, perhaps, but almost as cruel as those of the Bryce report.

Of course, every medical man in Germany is not a brute, for there are some exceptions to all rules, but all must expect to be accounted such so long as by silence they acquiesce in the brutal acts of their colleagues. Until the German medical profession as a whole repudiates those who have disgraced their calling we can have no dealings with any of the breed. The French scientific societies, including the Paris Academy of Medicine, have voted not to hold any intercourse with the scientists of Germany and Austria, and their example should be followed everywhere. We should go further, however, and refuse admission to fellowship to the present generation of German doctors. The State Boards, fortified by an act of legislature if necessary, should refuse to grant a license to practise to any man applying with a German diploma during the next twenty-five years, and even after that if those of the new generation still defend the crimes of their fathers.

THE "FEBRILE PANDEMIC."

SOME of the Italian authors are evidently not satisfied as to the identity of the present epidemic with influenza, as shown by the term "febrile pandemic" in current use. Thus Professor Minerbi in *La Riforma Medica* for October 19 makes some fundamental differences between the present pandemic and the accepted picture of influenza. The first, which refers to a peculiar incidence, attacking some while sparing other classes, may have only a local bearing and may be passed over. The second refers to the peculiar throat of the present pandemic —a punctate eruption in the velum, a redness of the cavum pharyngis, and edema—which apparently was never before noted. The third point of difference is in the absence of infection of the sinuses of the nose, which is a very common and burdensome complication of influenza, but scarcely present in the present pandemic. The fourth point is the notable difference between influenzal pneumonia of the textbooks and the severe types of the present pandemic. The differences are not alone in virulence but in anatomical type. Again, excepting these pneumonias, the present pandemic is singularly free from complications, while in influenza complications are extremely numerous and varied, in contrast with the monotonous character of the former. In the author's experience, at least,

the latter has never shown the enlarged lymph-nodes of the nucha and carotid sulcus which used to serve as a mark of recognition of beginning influenza.

If, however, we disregard the isolated epidemic of 1889 and study all of the recorded pandemics, the case is different; for, as shown by Professor Bozzolo in the same journal, in some of the older ones (beginning in 1585) there are unmistakable references to the complication of an asphyxiating pneumonia and other severe or unusual behavior not supposedly seen in influenza, as hemorrhagic rhinitis and other hemorrhagic manifestations. Despite this avowal the professor uses the expression "febrile pandemic" like his colleagues. The lesson here seems plain, for we must never base an account of a disease on a single pandemic but on all accessible records of like affections. The dualism of influenza was a trying problem before the pandemic of 1918, and certain textbook writers have felt obliged to give separate accounts of influenza and grippe. One author limits influenza to the effects of Pfeiffer's bacillus only—a doctrine which has now been superseded in all likelihood.

Sampietro in the *Annali d'Igiene* for September 30 states that the mortality from influenza in Italy was for 1890 0.389 per 1000 and in 1892 0.653 per 1000. The present epidemic in comparison with the old one is monosymptomatic for its own locality, yet the picture varies in different countries. In Italy exanthems were seen, in England polyadenopathy, and in Switzerland the Manchurian pneumonic plague was almost suggested. A study of old epidemics throws some light on this various behavior. Thus the author finds an account of a rheumato-catarrhal epidemic in Rome in 1782 also present in 1831 under the name "krip," which presented affinities with smallpox and especially with measles. Not only were symptoms of constitutional infection similar, but an exanthem was in evidence which was quite characteristic of the disease. In subsequent epidemics of influenza eruptions are sometimes mentioned.

As bearing on the question of contagion the author notes that grip patients from St. Petersburg who journeyed to Paris on express trains conveyed the disease from city to city in three days. This speed may of course be otherwise explained, but as far as the vitality of the germ is concerned its survival in the air is practically nil. During an epidemic of grip in Rome in 1709, the medical men were assembled to discuss it. The agreement was reached that the poor children of the city should be well nourished as a prophylactic measure, with milk, eggs, and meat. It is not recorded whether the recommendation was acted upon. The author is one of the first to note that no epizootic has yet accompanied the present pandemic. Epidemics affecting man and beast simultaneously have been recorded in 1693, 1732, 1767, 1775, and 1890. Despite the use of the term "febrile pandemic," there is nothing in the article which opposes a belief that the disease is influenza.

TYPHOID LESIONS OF THE CIRCULATORY SYSTEM.

Of recent years instances of embolus occurring during convalescence from typhoid fever have been reported with, it would seem, an increasing frequency. As an embolus must be preceded by an arteritis, phlebitis, myocarditis, or endocarditis, these lesions should always be looked for in typhoid cases. Typhoid arteritis, rare in children, is more common in subjects of from twenty to thirty years of age, and makes itself manifest at a time when recovery appears nearly complete, by a sudden severe pain in a limb, usually the right leg. By pressure over the internal malleolus, when the lower extremity is involved, a painful spot can be elicited which is of considerable diagnostic importance. Any movement of the limb is impossible without a recrudescence of the pain, while tingling or shooting pains are complained of. At the same time the local temperature is lowered. The vessel becomes more apparent and offers an exaggerated amplitude of the beats with each systole, contrasting with the local decrease of the blood pressure that is noted by the sphygmomanometer. These exaggerated beats indicate a paralysis of the vessel and loss of its elasticity. Then the blood pressure and amplitude of the beats progressively decrease and in some instances completely disappear. These signs indicate that a clot has formed and obstructs the lumen of the artery.

Palpitation of the vessel reveals a hard, painful cord, and in order of frequency come the posterior tibial, femoral, popliteal, anterior tibial, dorsalis pedis, arteries of the upper limb, the iliacs, and external carotid. A certain discordancy exists between the condition of the patient, who constantly complains, and the general temperature, which is not raised.

When acute arteritis involves the aorta the symptoms assume a special behavior. The patient complains of a sensation of retrosternal constriction of a painful type, with dyspnea and a dry cough. The carotids pulsate violently and sometimes the radial pulse is unequal. Dilatation of the aorta is made evident by an increase of dullness and an elevation of the upper border of the right subclavian. The second heart sound is doubled or there is a diastolic murmur at the base. The first sound is prolonged. Finally, signs of dry pericarditis may be detected at the base.

Phlebitis, like arteritis, occurs at the time of convalescence, while acute myocarditis occurs at the end of the second or at the commencement of the third week of the disease, its first manifestation being an erethism of the circulatory apparatus, soon followed by cardiac insufficiency. The pulse is small and compressible, the systolic wave is short, dicrotism is exaggerated, while at the same time there is tachycardia. The blood pressure falls. Another important sign is embryocardia, while a mitral systolic murmur may be detected due to functional insufficiency. There is cyanosis and the urine becomes dark and scanty.

Acute endocarditis following typhoid fever usually is ushered in by chills, a rise in temperature, restlessnes, and delirium. Auscultation reveals systolic or diastolic murmurs due to insufficiency or to stenosis of the orifices. They are remarkable for their early appearance in the evolution of the cardiac process. The murmur often assumes a musical tone, which has been attributed to vegetations or to floating tendinous cords which are put in vibration by the blood wave.

THE PSYCHOLOGICAL PERNICIOUSNESS OF PENSIONS.

When we come to consider a pension system for disabled soldiers, we have at once two diametrically opposed views. One is the popular, political, diplomatic, philanthropic, humane view of the masses, and can be expressed somewhat as follows: "Let us pension every soldier who has a genuine disability, and if in any cases there is doubt as to the genuineness of the disability, let us give him the benefit of the doubt and pension him too." Or as it was expressed by a famous Senator lately, "Perhaps they are not entitled to pensions, but I had rather grant six unjust claims than run the risk of letting one just one be denied." A fine statement. A heroic, noble, altruistic sentiment! But like some other fine things, just a little foolish. And, like most happy generalizations, not bearing the test of close examination very well. Suppose, for example, the six men in question are granted pensions. They know, deep down in their hearts, that they are not entitled to them. Furthermore, these gratuities are not enough to let them live comfortably, but merely enough to support them in semi-idleness, to enable them to support themselves at the homes of relatives, to engage in desultory occupations, and drift at last into an old age with no competence, no trade, and no stability of character. The soldiers' homes, the almshouses, and the insane asylums are full of veterans of the Civil and Spanish Wars, victims of just such circumstances. A life-long parasite on the public bounty does not go down to a green and honored old age.

It is a matter of general knowledge and comment, although few have dared, on account of the well-known American sentimentality, to call public attention to it, that the Confederate veterans, who had no pensions, did very much better in the world than the Union ones. The former were obliged to fall back upon themselves, to develop their own resources to the utmost, to overcome handicaps, and compensate for disabilities, so that they as a rule became self-supporting and have done well in the world, while north of the Mason and Dixon line the spectacle has largely been otherwise.

By all means, let us pension our soldiers who are really incapacitated, but where a doubt exists, let us examine the case fairly and carefully, always remembering that if the man is at all able to earn his living, we are bestowing a curse on him by pensioning him. It is far better to reconstruct or reeducate him so as to fit him to take his place in the world again. This may not be a popular view, but then the truth seldom is.

Quinine in the Prevention of Influenza.

With the menace of a return of the pandemic, like a wind which has veered to the opposite quarter, the question of prophylaxis becomes all important. It concerns the army surgeon in a manner seldom thought of in that all of his wounded under treatment may be unfavorably affected through the wounds going bad. The pregnant and puerperal woman is similarly menaced, and of course the great army of latent consumptives may be hurried along to the grave. Influenza has been styled a "pitiless Malthusian," a term perhaps previously applied to other maladies as well. Tricoire, a French army surgeon, says in an article in *Le Progrès Médical*, that with many wounded to care for he took up incidentally the subject of quinine prophylaxis of grippe. Naturally camps, boarding houses, convents, etc., are ideal for this study. Behind this is the prevention of commensal living when this is practicable, and even mere temporary assemblies. In a "planetary epidemic," as the present has been styled, a prophylaxis could hardly be too watchful and timely. In regard to quinine, he says, a dose or two, however large, is not to be thought of. The subject must become mildly saturated. In one barracks in which three soldiers came down with influenza the quinine prophylaxis was begun with one set of men, leaving an equal number of controls. Beginning with June 19 the first set received 50 cgm. daily for four days. Of unprotected men in the command, who numbered 53, the number stricken was 31, with average duration of 7 days and a fever of 38° C. average. Of the cinchonized men, who numbered 45, but 13 were attacked and laid up on an average of 3 days, while only 7 of the 45 ran a temperature which reached 38°. Long ago, in the laboratory, animals infected with Pfeiffer's bacillus were previously immunized with quinine sulphate injected into the veins; this experimental work suggested to the author the clinical application to his soldiers.

A Warning Against German Drugs.

The American Defense Society has given warning of the recent importation into the United States of $12,000,000 worth of drugs of German manufacture. The first lot came in at about the time that some German-made toys were sent over here, and since then other lots have arrived at various Atlantic ports, some being shipped in bond to interior points. Steps are being taken looking to the placing of an embargo, if possible, on future importations, and meanwhile physicians and druggists are urged to abstain from the use of any of these drugs already in the country. The reason for such action is twofold. In the first place, there is the natural repugnance of loyal Americans to have anything more to do with German goods; and secondly, American houses, having some time since begun, at considerable initial expense, to manufacture these drugs, we cannot, in fairness to them, permit the Germans to seize the market again and

by underbidding ruin this nascent industry. American chemistry in the process of emancipation from German dominion must not be allowed to fall again under subjection to the Teuton firms which fattened so long on American physicians and the American public.

News of the Week.

The Influenza Pandemic.—According to the estimates of the United States Public Health Service there have been, since September 15, 350,000 deaths from epidemic influenza and pneumonia among the civilian population of the United States. The records of the War Department show about 20,000 deaths from these causes in the army camps throughout the country. A comparison of the statistics of a number of the large Eastern cities shows that the death rate from influenza was less in New York than in any of the others, the rate being 27 per 1,000 population. The rate in Philadelphia was 54 per 1,000; Baltimore, 47 per 1,000; Boston, 41 per 1,000; Buffalo, 34, and Newark, 32 per 1,000. While the epidemic stage of the disease has long been passed, the number of cases belonging to the "grippe" group continues higher than the average of other years. A message recently received from Iceland declares that conditions on that island were never equaled since the black plague, and that 65 per cent. of the population of Reykjavik are down with influenza, the disease having apparently assumed its most severe and fatal form. The State Department has learned through its consul at Papeete, capital of Tahiti, in the Society Islands, that influenza has created a grave situation, and that the authorities have sent out an appeal for assistance.

Association of Life Insurance Presidents.—This organization held its annual meeting at the Hotel Astor, New York, on December 5 and 6, under the presidency of Henry Moir. In his presidential address, Mr. Moir stated that from a study of statistics he had reached the impression that the deaths resulting from the influenza epidemic approximated 400,000, which he said meant an economic waste of 10,000,000. The clear indication is that the deaths from influenza alone are but a fraction of the total caused by this epidemic. The average of all the companies was 13 per cent. from influenza alone, and 87 per cent. of deaths from pneumonia following influenza. This proportion is different from that indicated in the census bureau statistics. The average of all cases submitted was 33 years; in a well-established company the average age may be taken at 55 to 60 years. Major General Gorgas prepared a paper for the association, which was read by Col. William D. Wrightson, in which he pointed out the lessons in sanitation that the soldiers of the United States had gained in their camp life. He thought it was going to be very much easier in the future for communities to get appropriations for water and sewage systems. When soldiers get back home they will be desirous of applying what they have learned in their own communities so far as such application is possible. The greatest lesson of the war is the effect of crowding in large units. This is an important lesson, and will have its application in civil life. Crowding, and crowding in large units, play a capital rôle in the spread of septic pneumonia. Both overcrowding and segregation could be avoided by constructing the huts in cantonments 20 feet by 20 feet in plan and allowing not more than 20 feet to a hut. Compulsory health insurance was discussed by Dr. Frederick L. Hoffman, third vice-president of the Prudential Insurance Company, who stated that compulsory health insurance had been a complete failure in Germany. There its most lamentable consequences were a measurable lowering of the social and moral ideals and the individuality of the German people.

Lieut.-Col. Raffaele Bastianelli, professor of surgery in the University of Rome, has been elected an Honorary Fellow of the New York Academy of Medicine.

Dr. Edward H. Ellis has been elected a member of the Board of Health of Marlboro, Mass.

Dr. Harry Feagles has been nominated mayor of Morton, Wash., without opposition.

Charitable Bequest.—The will of Clara Sutton Macy bequeathes to St. Luke's Hospital and the Society of Hospitals, New York, $17,436 each.

The New York Academy of Medicine, at its anniversary meeting on December 6, elected the following officers: *President,* Dr. George David Stewart; *Vice-President, one-year term,* Dr. Reginald H. Sayre; *Vice-President, three-year term,* Dr. Charles H. Peck; *Recording Secretary,* Dr. Royal S. Haynes; *Trustee,* Dr. Walter B. James; *Member of Committee on Admission,* Dr. Frederic E. Sondem; *Member of Committee on Library,* Dr. Frederick Tilney.

Paris Pasteur Institute.—Dr. Pierre Roux, director of the Pasteur Institute of Paris for many years, has resigned, and will be succeeded by Dr. A. C. Calmette, director of the Pasteur Institute of Lille.

The Pasteur Institute of New York has been closed. This was the Pasteur pioneer on this side of the Atlantic, having been founded nearly thirty years ago. Dr. George Gibier Rambaud, who has been the head of the institute for some time, was a Major in the National Army and was ordered to France on active service. In his farewell address he stated that the reason for closing the institute was that it had fulfilled its purpose by introducing the Pasteur treatments which were now given in all well appointed hospitals. Since 1910 the institute has treated more than 10,000 patients, four-fifths of them without charge.

Effects of Poor Food in Austria.—According to Dr. Clemens von Pirquet, head of the Government Institute for Children in Vienna, the birth rate of the former empire of Austria-Hungary fell 50 per cent. during the war. The poor quality of the food has cut the total weight of the population one-third. It is common to find the weight of an average man reduced from 170 to 120 pounds. Dr. von Pirquet finds in his investigations that the big mistake of the entire world has been to waste food by misunderstanding its values. He has worked out a system by which to get practical results. He takes milk as the standard with a value of 1; on this basis dry flour has a food value of 5, which is the same as meat. Bread has a value of 3.3, and cabbage and vegetables only four-tenths. By apply-

ing his food system in the hospitals under his charge he has been able to feed children at a cost of 30 cents per child a day despite war prices. The rations provided by the food cards in Austria have permitted the population to get only one-third of the necessary nutrition. In Austria during the war all diseases have increased, but more particularly the lung diseases.

Deaths of Foreign Medical Men.—Dr. GAETANO RUMMO of Naples is dead. He was born in Naples, and after a brief sojourn in Genoa, following his graduation in medicine, he became associated with the chair of pathology in his alma mater. In 1885 he founded *La Riforma Medica*, and when we consider that this periodical was long issued daily, and was the only successful medical daily ever issued, we can reckon something of the personality of the editor. Rummo also collaborated in a number of other journalistic ventures. He left Naples to assume the chairs of pathology and clinical medicine in several of the smaller Italian universities, returning eventually to the medical clinic of Naples in 1894. Here he remained until his death. The sphere of his activities could hardly be exceeded. He was a laboratory man as well as a clinician and teacher, a sanitarian, publicist, practitioner, consultant, editor, statesman, and therapeutist, for unlike many scientific physicians he devoted much time to the study of the cure of disease. He made at least 120 contributions to current medical literature. These cover the entire field of internal medicine, neurology, and therapeutics.

Dr. KEY-ABERG, whose death was recently announced, was a well-known Scandinavian physician and scientist. He was born in 1854, and was graduated in medicine in 1887, his graduation thesis being devoted to endarteritis deformans. In 1889 he took up the practice of otology, rhinology, and laryngology. His writings deal largely, however, with medicolegal subjects and medical economics. For 30 years past he had held the chair of legal and forensic medicine in the Caroline Institute.

Obituary Notes.—Dr. SAMUEL ABBOTT GREEN died at his home in Boston, Mass., on December 5, at the age of 88 years. Dr. Green was born on March 15, 1830, in Groton, Mass. He was graduated from Harvard in 1851, and from the Harvard Medical School in 1854. He served as a surgeon in the Civil War, and was breveted lieutenant-colonel of volunteers for distinguished service. After serving as city physician and holding a number of city offices, Dr. Green was elected Mayor of Boston in 1882. He was a member of the board of overseers of Harvard for twenty years, librarian of the Massachusetts Historical Society for 30 years, a trustee of the Peabody Memorial Funds, and a member of various State boards. Dr. Green was the author of a number of books on the history of Massachusetts as well as a writer on a variety of medical subjects.

Dr. SAMUEL HOWARD MONELL, a graduate of Bellevue Hospital Medical College in 1890, died suddenly of pneumonia at his home in New York City, on December 5, aged 62 years.

Dr. RAFAEL RUBIROSA, formerly a well-known surgeon of the Dominican Republic, died in the Manhattan State Hospital, New York, on December 3, aged 33 years.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE PSYCHOLOGY OF PEACE—DEATH UNDER INTRAVENOUS INJECTION—THE LUNACY PATIENT AND THE OUTSIDE DOCTOR—ANOTHER STRIKE AT A LUNATIC ASYLUM—MINISTRY OF HEALTH BILL—THE INFLUENZA EPIDEMIC—DEATHS OF LT.-COL. E. F. HARRISON AND MEREDITH TOWNSEND.

LONDON, November 15, 1918.

THE psychology of peace is showing itself in London as I write, to be marked by features which are as distinct in their way as the psychology of war. As viewed in the streets, all the differences, and they are many, which mark the attitude and demeanor of the population can be summarized by saying that before eleven o'clock on the eleventh day of the eleventh month of the year everyone was braced against the shock of something that might be going to happen; after that hour no one cared what might be going to happen—at any rate it was not war. Although to-day is being held in peaceable revelry, young and old, man and woman, girl and boy, soldier, sailor, and civilian, all wandering in merry throngs about the streets, as they did yesterday and the day before yesterday, the celebrations of peace are all quite purposeless. Processions take no particular route; movements have no definite object; busses do not start where they should start from or arrive where they are expected; songs are begun but seldom finished; orators are hoisted to posts of vantage but what they say is not heeded. In every recurring phase of action and inaction among the crowd a complete lack of responsibility has taken the place for a brief time of the general mood of concentration which has marked the populace of London for four years. It is certain that most of the wild and happy revellers will return quite soon and with pleasure to their various avocations, for nothing is being done by the relaxed crowd that will unfit them for work at any moment when the call of duty makes a clear appeal. Vicious license, drunkenness, savage horseplay are all quite absent, or absent as any purposive attempt to celebrate peace in accordance with some large scheme of rejoicing. Everyone is just *déboutonné*.

A verdict of death from heart disease was recently returned at an inquest held on the body of a man who died at the Hampstead Military Hospital while undergoing an intravenous injection for trench fever. The particular procedure, it was stated at the inquiry, had been pursued with good success and without accident in 2000 cases, but as the syringe was being inserted, the patient suddenly collapsed and died almost immediately from heart failure. It is unnecessary to say that the death was chronicled in some newspapers as due to medical experimentation. These cases when a trivial operation is viewed by a patient with extraordinary apprehension, and endured by him with real and great pain, are a perpetual puzzle to those who always try to find a commensurate cause for every physical phenomenon in man. Why do many strong subjects faint during vaccination?

A case is attracting a considerable amount of attention in the medical world where the incidents

wear quite a sinister appearance, though no such interpretation of them would be in the least just. Dr. Lionel Weatherly is a well-known expert in lunacy, the proprietor at one time of a lunatic asylum, and the author of a breezy book upon the management of the insane. Dr. Weatherly was asked to visit a patient who was an inmate in a private capacity of a public or county lunatic asylum, that is, an institution where the regulations are in the hands of the Board of Control (Lunacy), a standing committee of the Home Office. Dr. Weatherly wrote to the superintendent of the county asylum and was refused permission to visit the patient. The relative who had given instructions to Dr. Weatherly, and Dr. Weatherly on his own account, then wrote to the Board of Control, both pointing out that under a section of the Lunacy Act such a permission to visit the inmate of an asylum could not be refused, save to an undesirable person, the same argument being advanced to the superintendent. Thereupon the Board of Control sent the necessary order of admission to the superintendent. But the visit, when made, turned out of little clinical or scientific value, as the superintendent and doctor in charge of the patient failed to meet Dr. Weatherly, who was also not supplied with the case-notes. Dr. Weatherly then wrote to the Board of Control asking for a second order of admission, together with special instructions that the patient's notes should be at his disposal. Whereupon the Board replied that there could be no need for Dr. Weatherly to see the patient again. The patient's friends are meditating legal action, or so it is announced in the press, but legal actions against Government Departments are apt to be costly futilities. But the official attitude has given the public every right to harbor all sorts of vague suspicions, none of which probably has any grounds whatever.

At the time when strike fever was running high all over England and Ireland, and appearing in a particularly ominous form in Scotland, I noted in one of my letters that in two cases the attendants at lunatic asylums had "downed tools," leaving two or three doctors responsible not only for the health and feeding of a singularly helpless and disease-ridden class, but for the discipline of a crowd who were in confinement exactly because discipline had no meaning for them. There was real apprehension in official circles lest the movement should spread, but so bitterly was popular sense against the strikers that no other instances than those which I recorded have since occurred until this week. But now 180 attendants at the large Irish lunatic asylum at Ballinasloe have gone on strike, with the result that 1,500 lunatics were left unguarded, just about one-quarter of whom were definitely homicidal, suicidal, or both. Fifty lunatics, including some of the most dangerous classes, escaped, and as I write some of these are at large. The attendants resumed work after a six hours' strike, and no doubt their financial grievances will be met. But who will meet the grievances, financial or worse, that may be inflicted on the community by the wandering lunatics?

The Ministry of Health Bill has arrived at a most unfortunate juncture so far as its immediate prospects are concerned, and no one is surprised that after having been read and printed, the House, or rather the Government, resolved not to proceed with it this session. With the sudden ending of war, and the vast problem of reconstruction awaiting solution, it was clearly inconvenient to engage upon the setting up a brand new State Department. The various processes of reconstruction may in themselves effect some of the reforms or remove some of the anomalies which in the Bill it was intended should be carried out or abolished, leaving for the immediate future more clear-cut issues for discussion. Nevertheless it is a disappointment to all those who have worked so hard to institute the new and necessary State Department to have their work so promptly set aside. All the work, however, has not been wasted. The proposals of many thoughtful men, arrived at by taking counsel of the recognized authorities, have been sifted, codified, and brought for discussion into the pages of a Parliamentary Bill. This Bill has been printed and therefore becomes available for study by both public bodies and interested individuals. When the measure, or one of similar scope, again comes up before the House of Commons, the criticism upon it should be enlightened, instead of merely eulogistic or destructive, and a really good bureau of national health should result.

The influenza epidemic is declining, but not so rapidly as the epidemiologists predicted. At many provincial centers, and some camps, the incidence remains severe; and if London is obviously recovering, Dublin and Belfast are in the throes.

The country owes much to the valuable and even unique work of Lieutenant-Colonel Edward Frank Harrison, whose death occurred just before the end of the war in which his service as a chemist proved so valuable. By his assiduous study of the poisonous gases used by the enemy and the means of protecting our own and our Allies' soldiers against such attacks he was instrumental in saving thousands of lives, devising masks containing an effective antidote. He was responsible for the admirable organization of the anti-gas section of the Chemical Warfare Department of the Ministry of Munitions, and he applied himself so thoroughly to the task that millions of respirators, the design of which was based on accurate chemical reasoning, were supplied to the Forces. This was no mean accomplishment when regard is had to the complex characters and the varieties of the poisonous gases employed. In pre-war days Colonel Harrison rendered valuable service by the work he undertook on behalf of the British Medical Association in the analysis of nostrums. This work resulted in the publication of two most valuable reports, "Secret Remedies" and "More Secret Remedies," in 1909 and 1912 respectively. In this work he evinced conspicuous analytical skill, justifying the responsibility of committing the results to publication. His evidence on these points was greatly appreciated by a Parliamentary Committee appointed to inquire into quack wares, and the report subsequently issued contains very valuable material available for useful reference at the present time. He possessed remarkable powers of organization and directed with great success a staff, mainly selected by himself, who were glad to work under so able a director. His death at a comparatively early age is much regretted by all who were associated with him, and

his valuable services to his country during the great struggle were recognized by the military honors accorded at the funeral. Harrison was gazetted a major-general just before his death, with complete control of his department, having thus had the remarkable record of enlisting four years ago as a private soldier at the age of 47 and reaching brigadier rank at 50.

The death has occurred of Dr. Meredith Townsend, who was recently Master of the Apothecaries' Society of London, which corporation he represented on the General Medical Council. Dr. Townsend was an active member of the Belgian Doctors' and Pharmacists' Relief Committee and initiated a successful collection of surgical instruments for the ruined Belgian doctors, housing the collection at and distributing it from the Apothecaries' Hall, City.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

REPORT OF THE COMMISSION APPOINTED BY THE ACADEMY OF MEDICINE UPON THE EPIDEMIC OF GRIPPE—NEW BELGIAN FIRST LINE HOSPITAL—ACTION TAKEN BY THE ACADEMY OF SCIENCE REGARDING FUTURE RELATIONS WITH GERMANS AND AUSTRIANS.

PARIS, November 11, 1918.

THE Under Secretary of State for the Sanitary Corps has requested the Academy of Medicine to study the question of the prevailing epidemic of influenza and recommend means to prevent it spreading to the army. The commission named by the academy was headed by Dr. Besançon, who has made his report. After showing that the incubation of the disease is of very short duration, he states that it would appear that one attack gives comparative immunity, and advises the quarantine or isolation of each case as it appears. In the family this is generally possible, but in the hospitals this is difficult, and the large number applying for entrance makes these centers a danger in spreading the disease. As a rule, there are insufficient rooms in which to isolate these patients. The next best precaution is to surround each bed by a framework at least 6 feet 6 inches high, from which sheets can be hung to entirely close it in. The patients should be evacuated the moment they are convalescent, and one should guard against overcrowding, which is the greatest factor of contagion. It is well also to consecrate a certain number of ambulances for the transportation of these cases and use them for no other purpose during the continuance of the epidemic. The public should not be permitted to visit patients except in rare circumstances. The grippe is most frequently taken in the common transport lines; and all of these conveyances ought to be disinfected at the end of each day. The public should be instructed during the continuance of the epidemic to rinse the mouth with antiseptic solution and carefully brush the teeth after each meal; the hands should be washed frequently during the day, and one should not remain long in the presence of a sufferer from the disease. All soldiers returning from furlough ought to be carefully inspected, with the fear that they could bring the contagion into the midst of their company; and finally, soldiers attacked by the disease ought to be placed in hospital where they are, and not sent to the interior, for traveling is as dangerous to them as if they were wounded, and equally dangerous for the public. Many of these precautions can be applied to the civil population, as, for example, the isolation of the sick, creation of special wards in a hospital. The precautions prescribed for individual hygiene, the disinfection of the different means of transportation, and especially is it recommended to the civil population to remain away from the theaters, cinemas, and all large public gatherings, and avoid, as far as possible, traveling in crowded conveyances.

Dr. Vincent, medical inspector of the army, followed the report with a paper in which he ascribed the contagion of the disease as attributable to the following causes: direct contact with the person, the linen worn by such a person, handkerchiefs, hairpins, hatpins, or anything that has come in contact with an afflicted person, and particularly the atmosphere which has been contaminated by one afflicted, the act of talking, coughing, sneezing, impregnates the atmosphere with the steam and saliva which carry the pathogenic microbes, and these find entrance into the system of the healthy person by way of the conjunctiva, the nasal fossa, the pharynx and larynx. To avoid the possibility of the contagion, Dr. Vincent proposes the wearing of a mask formed by five layers of gauze, covering the nose and mouth, contained in a transparent vizor which can be adjusted to the head, and possesses the advantage of cheapness and is easily sterilized. With respect to this recommendation, Dr. Bar said that in the Farnier clinic at least a third of the patients and hospital personnel had been attacked by the grippe; all of the others who in any way came in contact with the disease were furnished with a mask, which immediately checked the spread of the disease. Another curious fact which he observed was that out of 22 babies nursed by mothers who were suffering with the grippe, not one of them took the disease.

Drs. Schauffard, Ménétrier, Marphan, Ribemont, and Dessaiges believed that in infants under six months of age there was present, as in the very aged, a sort of immunity from the infection. Dr. Marphan stated that in his hospital service, in the wards reserved for nursing mothers there was not a single case of grippe among the children, whereas there were many cases in the other wards among the children from 1 to 15 years of age.

Explaining before the French Academy of Sciences the influenza discovery of two Tunis scientists, Dr. Roux, head of the Pasteur Institute, said that bronchial mucus taken from the sufferer and injected under the skin of a healthy man produced influenza in six days, but injections directly into the blood had no effect. It therefore appears that during the acute stage the bronchial secretions of patients are virulently infectious. The influenza germ, Dr. Roux added, is distinct from Pfeiffer's microbe. Dr. Legroux of the Pasteur Institute said that it may lead to the preparation of a preventive vaccine, which would be a protection both against influenza itself and the dangerous complications that so often follow. Its preparation, however, would involve long and difficult researches, so that there was no hope that it could be produced during the present epidemic.

"Send 100,000 yards of gauze and 2,000 pounds of cotton batting, also 25,000 enameled cups and plates" was one message received by the Belgian Commission on the morning the second lap of the Belgian offensive was started. They were started forward that night. Anticipation of a Belgian offensive led the Red Cross to prepare to meet every possible emergency. Five hundred thousand francs were contributed to help establish a modern hospital for Belgian soldiers at Vinckem, about five miles from the front. This is the main first-line hospital to which the wounded are taken in the present offensive on the Belgian front. Dr. De Page, the famous Belgian surgeon, and the Red Cross authorities cooperated in the construction of this hospital along modern lines. Wide corridors that could be turned into wards were a feature that proved serviceable when the capacity jumped from 250 to 1,500 beds.

The Academy of Science, by unanimous vote, has categorically declared that after the close of the war they will appeal to the Government to refrain from accrediting any savant of France to any scientific gathering or congress taking place in Germany or Austria-Hungary, and that their action be communicated to the scientific bodies of the allied countries. By unanimous vote the Academy of Medicine associated itself with the action of the Academy of Science.

4. Nonsurgical Treatment of Exophthalmic Goiter.—Israel Bram points out that since in Graves' disease irritation and hyperexcitability predominate, the most important element in the treatment is rest both of body and mind. Though opposed to hospital treatment, the author emphasizes the absolute necessity of strict discipline and considers the presence of a nurse essential in most cases. Regularity of sleep, rest, exercise, feeding, proper attention to bathing, the quality and quantity of foods and beverages, the kind of recreation to be indulged in, must all be given careful attention, and the doctor's orders carried out to the letter. Bram states that, except in cases where malignant changes are evident in the thyroid gland or where there are dangerous pressure symptoms, surgery is distinctly contraindicated. Hyperthyroidism is not a surgical entity, but is a disease which belongs strictly to the realm of the internist, for the following reasons: (1) Recent researches prove that Graves' disease is not a local condition, nor has it a local etiology; (2) though surgeons report very favorable surgical recoveries, clinical recoveries are rare, and in a vast majority of cases there is a postoperative return, occasionally with even greater vehemence of all the signs and symptoms of hyperthyroidism; (3) the patient who has been operated upon, and who does recover clinically, gets well because of a carefully outlined system of postoperative nonsurgical treatment, or because the case in question is one of those instances of spontaneous recovery and would have terminated favorably in spite of treatment; (4) internists who specialize in thyroid gland therapy cure more than 75 per cent. of their cases of hyperthyroidism by dietetic, hygienic, medicinal, and electrotherapeutic measures. The author adds that he has been able to cure nearly every case of hyperthyroidism that came under his care, and that this was accomplished by nonsurgical and remedial measures.

6. Pericholecystitic Adhesions: Their Importance and Clinical Recognition.—Frank Smithies points out that affections of the gallbladder commonly represent progressive infection of the structures forming the gallbladder wall, the infecting bacteria being blood borne. Pericholecystitic adhesions may be intrinsic in origin and occur as a consequence of changes primary in the gallbladder, or extrinsic and due to disease in neighboring structures. The term "pericholecystitic adhesions" signifies complications resulting from inflammatory processes arising in the gallbladder wall and involving the serous layer. The extrinsic origin of such complications is comparatively rare. Laboratory and clinical studies have shown that gallbladder disease is initiated by bacterial growth, the inflammatory reaction of the gallbladder wall being continuous and progressive (acutely or chronically) or intermittent. Pathologically, two facts are emphasized: (1) Extensive pericholecystitic adhesions may arise within a short time, should there be actively progressive bacterial invasion, or similar lesions may represent years of disease should the infecting organisms be of low virulence, the tissue defense strong or the extension of infection intermittent. (2) The clinical or histopathological study of pericholecystitic adhesions furnishes no clue as to the duration of the existing evidences of inflammatory tissue reaction. Though the author confines his remarks principally to a consideration of pericholecystic adhesions arising from disease in the gallbladder, he states that his personal observations during the past eight years have shown that lesions extrinsic to the gallbladder may be complicated by such adhesions frequently enough to render such complications important from the standpoint of diagnosis, prognosis, and therapy. Of 1,000 cases of intrinsic gallbladder disease there were pericholecystic adhesions in 489. In nearly one out of three cases these adhesions involved the bile ducts (cystic duct 24.5 per cent., common duct 5.4 per cent., hepatic duct 1.4 per cent.); in nearly one of four cases, adhesions reached the duodenum, and in more than one of ten cases they were attached to the stomach, commonly at or near the pylorus. Adhesions to the omentum, colon, and liver are frequent enough to merit consideration since they are often infected and represent bridges of inflamed serosa by which bacteria may be transplanted to viscera far removed from the initial focus. In 19.5 per cent. these adhesions involved two or more structures, the duodenum, pylorus, colon, and bile ducts being the most frequent locations of such

multiple adhesions. In 38.9 per cent. of cases the gallbladder contained calculi. The fact that in almost two-thirds of the cases stones were not found may be explained thus: that when rapid adhesions form, active, progressive infection causes exuberant inflammatory reaction in the serous coat of the gallbladder or lymph channels before great damage is done to the mucosa with consequent alteration in the gallbladder content or interference with free emptying of the viscus. In absence of the clinical history of gallstones, therefore, one is not justified in assuming that the gallbladder is not seriously at fault; in 4.2 per cent. of the present series there were no prelaparotomy symptoms or signs pointing to abnormality of the gallbladder or the digestive apparatus. The clinical symptoms and signs are briefly: Pain, which may be due to the passage of calculi or to adhesions interfering with the free emptying of the gallbladder. In both types of lesion "colics" may be severe, and there is little in the clinical history of pain to differentiate these two types. There was obstinate constipation in 62.7 per cent., diarrhea in 9.8 per cent., and normal motions in 27.4 per cent. of the author's cases. Nausea was troublesome in 18.2 per cent. and vomiting in 21.7 per cent. Jaundice was constant or intermittent in 18.8 per cent, and there was a possible history of jaundice in an additional 10.2 per cent. Abdominal tenderness was noted in 91 per cent. of cases; there was a palpable gallbladder tumor in 29 and an enlarged palpable liver in 18 cases. As to gastric function, complete test meal analyses are available in 370 cases; in 7.1 per cent. the emptying power of the stomach was interfered with. As to gastric acidity, the average free hydrochloric acid was 35.1, with a range of from 0 to 140; total acidity averaged 43.2, with range of from 4 to 146; combined acidity averaged 4.7, with range of from 0 to 19. Apparently, therefore, the gastric secretion does not vary greatly from the normal. Roentgen study of 211 cases of gallbladder disease complicated by adhesions showed that in the duodenum there was stenosis in 10, sharp permanent acute angulation of the intestine in 7, dilatation of the first two-thirds in 26, possible deformity in 49, and possible malposition or fixation in 23 cases. In this group there was gastric retention of the opaque meal in 13 instances. When the pylorus or stomach was involved there was deformity or malposition in 18 out of 32 cases, stenosis in 12, with 3 malignant cases, and six-hour opaque meal retention in 10 cases. In roentgen examination it is important to make serial plates, with the patient in different positions, before and after the administration of antispasmodic medicine. In the absence of clinical data indicating organic disease of the stomach or duodenum, roentgenograms showing gross anomalies of these viscera may be interpreted as indicating pericholecystitic adhesions.

The Lancet.

1. The Bradshaw Lecture on Neuroses and Psychoses of War.—Lieut.-Col. William Aldren Turner refers to the view of contemporary psycho-pathologists that all neuroses are "reactive" disorders, or consequences of a failure of psychologic adaptation or readjustment to environment. This is true particularly of the young soldier who is unable to adjust his outlook to service conditions; a large number of these men are constitutional neurasthenics, and any abnormal latent trend is quickly brought to the surface under the stress of camp life and military discipline. The most common type of mental psychosis observed in soldiers is a confusional psychosis, which may be superimposed upon a foundation of feeblemindness, or a basic reaction attributable to cerebral commotion, shell shock, or psychical trauma occurring in soldiers with a psychopathic inheritance. In both types prognosis is good, the condition lasting from a few days to several weeks. On the other hand, a confusional psychosis may be the early phase of an underlying and more deeply rooted disorder, such as dementia precox. The author, however, gives his attention chiefly to the different types of war neuroses, among which are the young and inexperienced soldiers who have given way to fear at their first experience of bombardment; those suffering from fatigue and nervous exhaustion, who require rest to restore them to duty; the cases of anxiety neuroses which occur generally in young officers, who in spite of insomnia, loss of self confidence, headache, mental depression, fear that they may be incapable of the adequate performance of their duty, that they may be considered cowards, etc., manage to carry on until some commotional shock—such as horrible sights, partial burial through shell or mine explosion, bad news from home, or a cerebral concussion or commotion from shell shock—may precipitate a breakdown and they become incapacitated. The effect of these traumata, and particularly the last, is the onset of stupor, delirium, or amnesia "fugue." Stupor may be profound with rigidity of the limbs of the catatonic type, or in milder cases the patient may appear dazed and confused, may be easily startled and more or less indifferent to his surroundings. The stupor may be followed by mutism, deaf mutism, aphonia and stuttering; mutism has been explained as a state of functional inhibition, due to fear or horror which underlies the stupor. Astasia abasia is another symptom which may follow stupor and which is often accompanied by anxiety, the patient being obsessed by a fear that he is unable to walk. These disabilities, if left untreated, soon become "habits," develop into "war hysterias" and eventually "defence mechanisms," which though developed unconsciously, persist as reactions against various contingencies, chief of which is a desire not to return to any form of active warfare. Anxiety neuroses and anxiety depression are common symptoms of war neuroses which may occur alone or in association with mutism and paralytic symptoms, the chief feature of which are the "terror dreams," the patient going through a pantomime of fighting during sleep and waking up suddenly bathed in perspiration. Recovery in such cases may be estimated by the degree and frequency of these dreams. In a number of instances, such symptoms persist as a result of memories of experiences in earlier life which are revived in dreams, and are added to the war dreams. If such patients can be brought to realize the nature of their trouble the anxiety will lessen and frequently disappear. An objective sign of anxiety neurosis is a profound loss of body weight, associated with lowered blood pressure and an unusual degree of fatigue. Many such cases will recover with rest and quiet and attention to sleep; others require special psychotherapeutic attention, and others again—if the mental disorder has been fixed and systematized—may not recover. In a general way, it may be said that neurasthenia is more common in officers and objective symptoms of hysteria commoner in men. An explanation of this may be found in the greater responsibility of the officer. Turner points out that a sufficiently clear distinction has not always been drawn between symptoms which arise in consequence of physical and psychical causes respectively. Among earlier observers there was a tendency to underestimate the psychical factor and a school of French neurologists in particular has laid stress upon the importance of "cerebral commotion" in the causation of the psychoneuroses of war. The modern school of psychopathologists, on the other hand, may incline too much in the contrary direction. Some French neurologists draw a distinction between direct and indirect concussion. In the former, the symptoms are those of structural lesions of the central nervous system, such as muscular relaxation and hypotonia, impairment or abolition of deep reflexes, pressure of an extensor plantar response, retention of urine, hemorrhage into retina, voltaic vertigo, etc. Examination of the cerebrospinal fluid during the first two or three days following shock may exhibit blood staining, raised pressure, increase of albumin content, and sometimes a

lymphocytosis. Such signs may be transitory, but in a day or two other signs may be noted. In indirect concussion there is no visible external injury, but a cerebral commotion is produced indirectly. It is unlikely that concussion gives rise to anxiety unless this neurosis was in process of development at the time of the shock. In the treatment of war neuroses practical experience has shown that the hysterical symptoms can be cured rapidly and effectually by psychotherapy consisting of suggestion, persuasion, and re-education. Anything, however, that suggests to the patient that he is suffering from serious disability of organic nature will retard recovery—for example, repeated change from one hospital to another; treatment at spas, where too great attention to therapeutic measures tends to fix the neurosis in the patient's mind; or too much sympathy or hero worship. Experience has shown that treatment is best carried out in special hospitals under specially trained medical officers, where patients may be studied individually. It is important that symptoms should be given proper treatment while they are removable and fluid and before habit has been established. The French realized this early in the war and established neurological centers in the zones of their armies, and this example was followed by the British in the winter of 1916-17.

2. "Spacing Out" in the Prevention of Military Epidemics of Cerebrospinal Fever.—Captain J. A. Glover enumerates the main etiological factors which appear to produce military outbreaks of cerebrospinal fever, namely, (1) Season—the first quarter of the year; (2) Severe weather of all kinds and particularly sudden variations, east winds, and intense cold; (3) Antecedent epidemics of influenza; (4) Causes temporarily lowering resistance, such as antityphoid inoculation, fatigue, strenuous training, nostalgia, railway journeys, and the strangeness of barrack life to the new recruit; (5) Overcrowding; (6) A high carrier rate of epidemic strains of the meningococcus in the population at risk. He points out that while the first two factors are beyond our control, and the third and fourth largely so, the fifth and sixth are entirely in our hands and are indices of the efficiency of our sanitary stewardship. After four years of war no plea of military necessity for overcrowding can be accepted, and by "overcrowding" is meant the slightest excess over the "mobilization standard," when beds are approximately 1 ft. 4 in. apart. Overcrowding influences the incidence of cerebrospinal fever by its depressing effect, and by shortening the distance between man and man and thus facilitating transmission of infection. Captain Glover illustrates his remarks by the meningococcal history of a certain camp, where overcrowding was followed by an increase in the carrier rate, the "warning rise," to over 70 per cent., and an outbreak of the disease. The following September, prophylactic measures were put into force; beds were spaced out to 2½ ft. distance, ventilation was improved, and antityphoid inoculation postponed until the recruit's second month. As a result, the carrier rate fell steadily throughout the winter and in February, 1918, was 4 per cent. compared with a maximum of 72 per cent. twelve months previously. When overcrowding again began in April, the carrier rate rose from 1 per cent. on April 10th, to 31 per cent. on May 2nd. It is significant, however, that cases which then occurred were due to Types I and III, whereas the previous outbreak had been due to Type II of the meningococcus. Captain Glover sums up his conclusions as follows: (1) A high carrier rate usually denotes overcrowding and dangerously unhygienic conditions, even though no cases of the disease may have recently occurred; (2) Whilst sporadic cases may occur in a military as in any other community with any carrier rate, anything approaching an epidemic of cerebrospinal fever is heralded by a warning rise of considerable height in the carrier rate; (3) Severe overcrowding will probably be accompanied by a carrier rate (serological) of at least 20 per cent. This percentage is indicated as the danger line in the *War Office Memorandum* on Cerebrospinal fever (March, 1917). A carrier rate of this height will usually imply that the mobilization standard of 40 sq. ft. per man has been infringed, and that beds in the unit examined are less than 1 ft. apart. It should be regarded as a signal for prompt and effective action to diminish overcrowding, and to improve ventilation; (4) The distance between beds is of paramount importance; (5) Carrier rates between 10 and 20 per cent. are unsatisfactory, and imply a certain amount of overcrowding, and must be watched with suspicion; (6) Carrier rates from 2 to 5 per cent. may be considered usual under the best conditions obtainable in barracks and hutments; (7) Under the same conditions of overcrowding "non-contacts" carrier rates agree substantially with "contact" carrier rates; (8) Quite a moderate degree of "spacing out" of beds combined with simple methods of improving ventilation are highly efficient agents in reducing high carrier rates; (9) When a unit shows a high carrier rate, a distance of at least 2½ ft. between the beds should be enforced. The "peace" standard (3 ft. between beds) would, of course, be even more effective; (10) Recruits should be specially spaced out during their first three months of service.

6. Chemistry of Measles and Scarlet Fever. S. Velazquez de Castro.
7. Medical Aspects of the War. F. M. Fernandez.
8. A Case of Rat-bite Fever. A. Matienzo.

2. Convenience of Treating Old Cases of Atrophy of the Optic Discs.—Juan Santos Fernandez, describing some cases of optic nerve atrophy of long standing, gives his reasons for recommending that even in these old cases treatment should be instituted, because there is always the chance that they may improve somewhat.

4. A Social Danger.—Victor Foveau refers to the disadvantages of the obligatory registration of tuberculous cases as it was intended to do in France. The large number of tuberculosis cases makes it impossible for the State to keep them isolated.

6. Chemistry of Measles and Scarlet Fever.—S. Velasquez de Castro denies that either one of those diseases has a bacterial origin. He believes that in both cases there is some dietetic cause, there being a slight arsenicism in the first case and a slight iodism in scarlet fever. The author bases his opinion on the fact that overdoses of arsenic or of iodides cause symptoms similar to those seen in one or the other of these diseases.

Berliner klinische Wochenschrift.

October 7, 1918.

The Appearance of External Heterosexual Characters in Hypogenital States.—A. Alexander relates the case of a woman, age 34 years, without children. Since the absence of her husband the menses progressively diminished and had ceased to appear. The writer found a notable atrophy of the uterus and at the same time there had appeared distinctly masculine characteristics. The voice had changed, a minute beard developed, as

well as other changes in the epilous system. The writer explains this syndrome by a constitutional hypoplasia of the female endocrine apparatus and this hypoplasia ends in an insufficiency. At this time the heterosexual characters appear as they are no longer under the control of the female internal secretion.

The Frequency and Signification of Scaphoid Scapula.—F. Chotzen has studied the malformation described by Graves (MEDICAL RECORD, May 21, 1910), consisting of a concave internal border of the scapulæ. The writer seems to be very broad in the attribution of this condition since he has found 270 instances out of a total of 400 children in the schools for weak-minded at Breslau. Chotzen was unable to discover a luetic origin in his cases although this is supposed to be the case by most writers. On the other hand, the history of rickets was common in the children affected. The malformation is frequently accompanied by other evidences of degeneration. Among the children with scaphoid scapula, mental insufficiency reaching to manifest idiocy was found in ten cases, five of which were instances of mongolian idiocy. Examination of 550 soldiers in active service showed that 19 per cent. had scaphoid scapula and in them the history of hereditary syphilis was not more common than in the others, but as in the case of the children the history of rickets was frequent.

Gastric Sensitiveness to Cold.—E. Melchior states that liquids are not perceived by the gastric mucosa but they are by the abdominal parietes, which become cold when cold fluids are taken into the stomach.

Münchener medizinische Wochenschrift.

September 24, 1918.

The Epidemiology of Malaria.—Kirschbaum shows that in a region where malaria is not endemic the disease may be introduced by carriers of the plasmodium and develop among others from mosquitos which have sucked the blood of the carriers. The heat of spring is the determining factor of the recrudescence which occurs at this time of the year. The writer shows by charts the dependence of the number of new cases on the daily thermic changes. There is no hibernation of the plasmodium in the anopheles; the recurrence of epidemics of malaria in the spring is due to human carriers. The latter may be infected in a latent state until the time of their invasion in the spring. The climatologic conditions of summer are unfavorable for the development of the plasmodium in the interior of the anopheles and explain the frequent latency of the disease during this period of the year. From the viewpoint of prophylaxis quinine is indicated in armies where latent affections become suddenly declared. In order to avoid relapses and diminish the number of carriers, it is necessary to examine patients twice after their apparent cure at intervals of one month.

Fat Embolus as a Cause of the Phenomena of Past Traumatic Shock.—H. Siegmund opposes to the generally accepted nervous theory of shock, another interpretation based on twelve autopsies. In all these cases the clinical signs had been those of serious shock ending in death within a few days. The special histological coloration revealed the presence of fat cells in the arteriolæ and pulmonary capillaries. The general circulation also showed fat globules even when Botal's foramen was perfectly closed. These emboli were also found in the cerebral, renal, splenic, and cardiac vessels. Control researches showed that these emboli are met with in cases other than fracture as, for example, in infectious diseases, but in this case the emboli are never in such considerable numbers as in states of shock. In the case of rapid death (falls in aviation) fat emboli are found, which proves that this complication may occur with extreme rapidity. The writer insists on the importance of the mechanism of embolus in a series of affections having commotional and convulsive phenomena.

Deutsche medizinische Wochenschrift.

September 26, 1918.

Hemoglobinuric Bilious Fever.—Mühlens studies this complication of malarial states without bringing forward much personal work. The distinctive signs of the attack are a sudden onset with chills and fever, vomiting, a serious general condition, hemoglobinuria with icterus and a marked anemia, tumefaction, and pain of the spleen and liver. The mortality, according to various statistics, varies from 10 to 50 per cent., and especially according to the possibilities for treatment. The blood contains the plasmodium before the attack and is present for one or two days during it. During the attack the schizontes must be destroyed as well as the erythrocytes. After the attack they gradually reappear. As to treatment, the writer advises cardiac tonics, abundant diuretic infusions, physiological salt solution, etc. Calcium chloride and cholesterin, which are supposed to diminish the globular fragility, gave no very marked results at the writer's hands. It is now generally considered that quinine should be omitted at the time of the attack and the instructions of the German Health Service are to this effect. After the attack, quinine should be given by slowly increasing daily doses, beginning with 1 centigram and gradually attaining one gram per diem. The urine must be carefully watched in order to detect the first traces of urobilin or albumin which are the index of an approaching attack of hemoglobinuria. Methylene blue possesses the same drawbacks as quinine and should not be employed.

The Relationship Between Malaria and Leucemia.—G. Rosenow reports the case of a soldier who, after attacks of malaria, developed a myeloid leucemia (113,000 white corpuscles). The relation between cause and effect appears evident to the writer and it is to be remarked that the occurrence of new attacks of malaria made a drop in the number of white cells. This fact is to be regarded as an exaggeration of the usual phenomenon of leucopenia at the time of malarial paroxysms.

Some Symptoms of Latent and Tropical Malaria.—F. Sachs mentions as such, persistent headache, neuralgic or rheumatismal pain, bronchitis, intestinal disturbances and icterus. These signs, even in absence of hematologic or clinical evidence, should draw the physician's attention to the possibility of malaria which should then be looked for by the well known procedures of provocation.

Correspondenz-Blatt für Schweizer Aerzte.

August 31, 1918.

Traumatic Nephritis.—Wildbolz, after mentioning the special interest of this substance for accident insurance, states that doubt as to the existence of this lesion still obtains. No one denies its possibility, but none the less it is very difficult to commit one's self to a hard and fast diagnosis, such as must be forthcoming in insurance practice. If numbers of alleged cases signify anything, traumatic nephritis not only exists but is fairly common. But when one reads all of these histories through, the relationship of cause and effect is always uncertain. If a man of continuous good health gets an injury in which the kidney is directly implicated and if renal elements which signify inflammation can be found in the urine and if there is a constitutional reaction such as accompanies nephritis then one can speak of a traumatic nephritis. On the other hand, if high blood pressure and dilated heart appear after the injury it can only mean an old nephritis which has been aggravated by the injury; for such sequelæ could not develop rapidly. A contusion over the kidney may cause a certain amount of mechanical disturbance ending in desquamation with leakage of albumin and slight hemorrhage, but this soon disappears and should not be termed traumatic nephritis. Exploratory palpation of the kidneys may also cause the appearance of a renal sediment in the urine. Unless the trauma alone and at once causes the appearance of a renal sediment the author would not use the term traumatic nephritis. A case is related of a carpenter who was struck over the loins by a falling joist. He kept at work with both local and general symptoms and the examining physicians reported no damage although they failed to examine the urine. Becoming worse, he took his urine to a druggist who found an abundance of albumin. He then consulted the author, who at once examined him for pre-existing nephritis, as shown by the state of the cardiovascular system. There was an

effort to differentiate between the two kidneys, as presumably one bore the brunt of the injury. Ureteral catheterisation was performed and when it was learned that both kidneys were equally compromised the author decided against traumatic nephritis. It seldom happens that any of these patients have their urine examined directly after the injury. Several complete cases are cited—injury over one kidney, initial hematuria, interval of latency, evidences of nephritis shown by segregation to be unilateral, etc.

La Presse Médicale.

August 15, 1918.

Clinical Consequences of Oliguria of Cardiac Origin.—Josue and Parturier state that the elimination of urine diminishes in asystolia because of slowing of the circulation and renal stasis. The oliguria in turn reacts on the kidneys and the resulting troubles are superadded to the asystolia. In this way renal symptoms may come to dominate the picture. The traditional belief is that it is often difficult to distinguish between a cardiac and renal lesion in these cases. In such a dilemma a cardiac stimulant will often clear up the renal symptoms. The authors call this syndrome the pesudo-cardiorenal because in this type of affection there is no actual renal lesion present. As a matter of fact, oliguria in these cases can lead to the same edema and the same retention in the blood that we see in uremia. The authors have seen many cases in which nitrogen retention amounted to 1 gm. per liter of blood. But if the heart be stimulated by digitalis, the kidney, as already stated, clears up promptly. The mechanism here is of the simplest, according to the authors, although this is not universally conceded. The syndrome comes about purely from water stagnation and vanishes with diuresis. Others hold that some of the renal parenchyma is actually compromised. The water retention causes edema and hydremia. The edema of the blood so-called becomes edema of the tissues. Retention of water means a parallel retention of sodium chloride, the salt being dissolved in the water in a constant concentration. Urea retention, while present in marked degree, even sometimes tenfold normal, never reaches such a figure as to cause uremia. In other words nitrogen and chlorine retention are not parallel in asystolia. The scanty urine of the latter condition contains plenty of urea, but is poor in chlorides, because of the notable retention of the latter. Should a pathological azotemia develop in these cases, it is certain evidence of a renal lesion.

La Presse Médicale.

September 12, 1918.

Mitral Stenosis and Raynaud's Disease.—Chalier alludes to the complex etiology of Raynaud's disease and has repeatedly called attention to a relationship between the latter and vascular lesions. A few cases are on record of association of the peripheral lesion with mitral stenosis while in a much larger number some other lesion of the heart was in evidence. These comprise interventricular communication, aortic insufficiency, angina pectoris, pulmonal insufficiency, tricuspid insufficiency, cardiac hypertrophy, etc. To these totals may be added an entire large series of cases of arteriosclerosis, atheroma, and combinations of cardiac and vascular disease. The author is interested in this connection only in mitral stenosis and is now able to cite six personal cases of the association with Raynaud's disease to the older material. All six presented the double affection in greater or less purity and in all the cardiac lesion evidently preceded the Raynaud's disease. This fact, with the admitted infrequency of the latter, shows plainly that the cardiac affection was a causal element or concomitant in the genesis of the gangrene. Much must depend on the nature and cause of the endocarditis which was responsible for the stenosis; and if we assume that this was articular rheumatism then we might add the large number of other cardiopathies of presumably the same origin and make rheumatism a potent factor in the causation of Raynaud's disease. But on interrogation of the patients we singularly enough find no history whatever of rheumatism in three of the six. The next causal factor to consider is tuberculosis which may cause mitral stenosis in some indirect fashion, probably by action of the toxins on the endocardium. There is considerable resemblance also between certain tuberculides of the fingers and Raynaud's disease. But in three again of the author's cases there were no data to suggest tuberculous infection. We can only conclude that the same factor or factors which set up Raynaud's disease may also give rise to the cardiac lesion. The vasomotor system is probably involved in the mechanism in the latter as it is in the former.

Wiener medizinische Wochenschrift.

August 31, 1918.

The So-called Disasters from Salvarsan.—M. von Zeissel has observed 4,000 syphilitics treated with salvarsan and found that many offered certain disturbances, such as erythemata, urticaria, or vomiting. Without bringing forward any cases of more serious accidents resulting from salvarsan, the writer refers to certain accidents, such as blindness, deafness, and nervous lesions present in cases of syphilis at the time they came under treatment.

The Struggle Against Infectious Diseases in the Army of the Isonzo.—K. Russ, in this second portion of his article, after referring to the installation of baths and lice disinfection, speaks of the service rendered by laundries and centers for examination of foodstuffs. Prophylactic vaccinations were made every three months for cholera and every seven months for typhoid. In certain formations a mixed cholera-typhoid vaccine was tried. Antidysenteric vaccination is being studied. The results of these measures are shown by statistical charts made by the writer. They reveal a general decrease in the death rate for the various diseases, particularly marked for six months beginning with January, 1916, after which it fell more slowly. October, 1916, shows a general recrudescence of the diseases but they were mild in severity and very temporary in duration. The eruptive fevers (measles, scarlet fever, and typhus) were few and sporadic. There were some few cases of cerebrospinal meningitis but the mortality was high, viz.: 50 per cent. in spite of serotherapy. The great infrequency of tetanus is attributed to prophylactic injections.

Norsk Magazin for Laegevidenskaben.

August, 1918.

Idiopathic Dilatation of the Esophagus.—Harbitz calls attention to the similarity which exists between three different affections of the alimentary canal, viz.: congenital megacolon or Hirschsprung's disease, pyloric hypertrophy and stenosis in the new born or very young infant and idiopathic dilatation of the esophagus. Concerning the latter, he has seen three cases in individuals respectively 34, 40 and 27 years of age, all of them being autopsy cases. The first patient was believed to suffer from gastric ulcer or cancer. The symptoms were great emaciation and rejection of food and his disorder had begun 8 years before with swallowing troubles. Even after admission to the clinic of Professor Nicolaysen the diagnosis of gastric cancer was upheld and an exploratory laparotomy which resulted in the patient's death led to the autopsy diagnosis. In the second case idiopathic dilatation of the esophagus was recognized by the *x*-ray. Death took place three days after laparotomy performed with the intent of separating the cardia from the hiatus of the esophagus. The third patient had been treated for stenosis of the esophagus. He was subjected to a gastrostomy and died of postoperative pneumonia.

Case of Congenital Dextrocardia.—Barth's patient suffered from ulcerative endocarditis in a right sided heart. The age was seventeen years and although the boy had been under medical care before it had never been remarked that the heart beat was on the right side. The present illness began two weeks before as a remittent fever. The author had no trouble in the diagnosis of dextrocardia of evident congenital origin with ulcerative endocarditis. Death took place from hemiplegia following cerebral embolism. Autopsy showed an ulcer on the mitral and the presence of half a pint of clear fluid in the pericardium.

Book Reviews.

THE SURGICAL CLINICS OF CHICAGO. Volume 2, Number 3, June, 1918. Octavo of 254 pages with 63 illustrations. Published bi-monthly. Price, per year, $10.00. Philadelphia and London: W. B. Saunders Co., 1918.

THIS number of the clinics contains fifteen clinical lectures covering a great variety of subjects, from renal calculus and gallstones to bunions. Bevan's lectures are based upon six clinical cases of various kinds and fill about one-fifth of the book. Smithies contributes a long lecture on gall-bladder disease, partly based on a number of clinical cases and partly on a study of 1000 cases in which gall-bladder pathology was demonstrated by operation. Carl Beck describes a new method of performing gastrostomy. E. H. Ochsner has an interesting lecture on the treatment of flat foot. Buford gives the results of his experience in the treatment of umbilical hernia in children. There are several other lectures that well merit individual notice, and the number as a whole is particularly good.

GYMNASTIC TREATMENT FOR JOINT AND MUSCLE DISABILITIES. By Brevet Col. H. E. DEANE, R.A.M.C. Price, $2.50. New York: Oxford University Press, American Branch, 1918.

THIS little volume contains 26 photographs which illustrate chiefly various gymnastic exercises. The apparatus recommended includes the so-called "handbag" which can be indented by a certain degree of finger pressure, Indian clubs, the skipping rope, wrist rollers and pulley machines, the climbing rope, parallel bars, the climbing plank, walking and hanging beams, wall bars, and the nautical wheel. Free gymnastics and games are also illustrated. One aim of these exercises is recovery of lost function; another is increased development of sound limbs.

CLINICAL DISORDERS OF THE HEART BEAT. A Handbook for Practitioners and Students. By THOMAS LEWIS, M.D., F.R.S., D.Sc., F.R.C.P., Physician of the Staff of the Medical Research Committee; Assistant Physician and Lecturer in Cardiac Pathology, University College Hospital; Late Physician to Out-Patients, City of London Hospital for Diseases of the Chest. Fourth edition. Price, $2.25. New York: Paul B. Hoeber, 1918.

THERE is little to add to what has already been said regarding this book in reviews of the earlier editions. The subject of the heart's action as studied in the pulse and by graphic methods is one that Lewis has made peculiarly his own, and what he has to teach us in this line is worthy of the careful attention of clinicians. Whatever advance there has been in this study during the past two years is recorded in this new edition, which can be recommended as a trustworthy guide to the diagnosis of disorders of the cardiac muscle.

AMPUTATION STUMPS: THEIR CARE AND AFTERTREATMENT. By G. MARTIN HUGGINS, F.R.C.S., Medical Officer to the Government Schools, Salisbury, Rhodesia; Late Surgical Specialist to the Pavilion Military Hospital, Brighton. Pp. 228, with 95 illustrations. Price, $2.75. London and New York: Oxford University Press, American Branch, 1918.

THIS guide in the treatment of cases in which amputations have been performed was written because very little information on the subject has been published heretofore in such shape as to be readily available. The author's qualification rests in the fact that as surgical specialist at the Pavilion General Hospital at Brighton for 13 months he was responsible for the treatment of about 3000 amputation cases in the course of a year; and he also visited Roehampton House once a week to see his own and other surgeons' cases fitted with artificial limbs. This afforded a wonderful opportunity to see large numbers of good and bad end results so that it was possible to come to definite conclusions as to the best methods of treatment and, *per contra*, the methods to be avoided. This book is not intended as a textbook on amputations, and the author assumes that the reader is familiar with the information contained in the ordinary surgical textbooks.

The book is divided into seven chapters under the following titles: General Considerations; Amputation Stumps of the Upper Limb; Amputation Stumps of the Lower Limb; Painful and Tender Stumps; Sinuses and Necrosis of Bone; Joint Deformities; and Miscellaneous Considerations, Temporary Peg Legs, etc. This transcript of the chapter headings will give an approximate idea of the ground covered. Unfortunately, space will permit but very limited discussion of the text. In the chapter on General Considerations the qualities of the ideal stump are set forth. This is followed by remarks on the guillotine operation, when to reamputate, evidence that the stump is ready for reamputation, the technique of reamputation, pain following reamputation, etc. These remarks are eminently practical and are based upon such an extensive experience that they are almost invaluable, which, indeed, may be said of practically the entire text. Throughout, in the chapters discussing regional amputations, the possibilities and limitations of subsequent mechanical appliances are kept well in the foreground. The book is adequately illustrated and is of the greatest value just at the present time when so much reconstructive work along this line is to be done.

THE AMERICAN HOSPITAL OF THE TWENTIETH CENTURY. A treatise on the development of medical institutions, both in Europe and in America, since the beginning of the present century. By EDWARD F. STEVENS, architect, member of American Institute of Architects; member of Province of Quebec Association of Architects; member of American Hospital Association. Illustrated. New York: Architectural Record Publishing Co., 1918.

THERE is a paucity of books dealing with American hospitals. It certainly is not because hospitals of this continent are not equal to those of Europe. Rather it may be said that in many respects institutions for treating the sick are models, on this side of the Atlantic. Mr. Edward F. Stevens, the well-known Boston architect, in the work before us has endeavored to remove to some extent the reproach from America that her numerous splendid hospitals are inadequately described. The author is particularly well qualified for the task as he has himself designed some of the most notable American hospitals. The work well fulfills its purpose and is profusely and suitably illustrated.

AN INTRODUCTION TO THE MAMMALIAN DENTITION. By T. WINGATE TODD, M.B., Ch.B., Manc.; F.R.C.S., Eng.; Captain Canadian Army Medical Corps; Payne Professor of Anatomy, Western Reserve University, Cleveland, Ohio. Price, $3.00. St. Louis: C. V. Mosby Co., 1918.

THIS volume is in addition to its technical features a document relating to the evolution of the mammals. As far as the teeth can witness the latter had as progenitors certain mammal-like reptiles known as therocephali and cynodonts, both of which show rudiments of mammalian teeth in addition to other mammal-like features. These reptiles walked rather than crept, through the possession of well-developed limbs, and this high degree of locomotive activity may have played a role in the development of warm blood. Dental evolution assumed more and more the mammalian type but a genealogy based purely on dentition is evidently incomplete. The earliest known mammals appear to have been marsupials and certain insectivora. Forms of the latter, known as tree-shrews, may have evolved into the lowest primates and these into the higher forms.

THE CANADIAN MEDICAL WEEK. Hamilton, May 27-June 1, 1918. Published under the auspices of the Ontario Medical Association. Price, $4.00. Toronto: The Macmillan Company of Canada, Ltd., 1918.

THIS volume contains the transactions of a joint session of the Canadian and Ontario Medical Associations, which was carried out in nine sections, viz., eye, ear, nose and throat; medicine; obstetrics and gynecology; pediatrics; public health; returned soldier problem; surgery tuberculosis; museum and laboratory. About 50 papers were read, nearly half of which were by physicians of the United States, doubtless because of the absence abroad of so many prominent Canadians. The range and quality of effort in the contributions are both notable.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Thirtieth Annual Meeting,

Held at Lenox, Mass., May 27, 28 and 29, 1918.

THE PRESIDENT, DR. LINNÆUS EDWIN LAFETRA OF NEW YORK IN THE CHAIR.

(*Continued from page* 1006.)

Variations in the Lipoid ("Fat") Content of the Blood of Infants Under Certain Nutritional Conditions.—Drs. W. MCKIM MARRIOTT of St. Louis and WARREN R. SISSON of Boston presented this paper, which was read by Dr. Marriott. He said that an infant fed on considerable amounts of fat, but unable to utilize this fat, was virtually in a state of fat starvation. Analysis of the stools for fat or its derivities gave us some indication of the efficiency with which the fat of the food was digested and absorbed. Further information as to the behavior of fat in the body of the infant could be obtained from a study of the fat of the circulating blood under varying conditions of feeding and states of nutrition. Blood fat was derived from the tissues as well as from the food, and during complete starvation might be as high as when moderate amounts of fat were fed. In order to interpret the analysis of blood for fat it was necessary to know the diet of the patient. If the food taken was what would ordinarily be adequate, and blood fat remained low, it might be assumed that there was difficulty with fat absorbtion. A high blood fat meant a deposition of fat somewhere in the body. Blood fat was determined by Bloor's nephelometric method. The authors had made 52 determinations of fat on the bloods from 48 infants, patients in the wards of the Boston Floating Hospital. The average blood fat for the series was 0.68 per cent. There were no differences in the blood fat percentage that could be attributed to the time of taking of the samples after feeding. Other factors being equal, well nourished and poorly nourished infants had essentially the same amounts of fat in the blood. Their results showed that an infant who was gaining weight, no matter what his state of nutrition, would have a higher blood fat percentage than one who was not gaining. Breast fed infants gaining weight showed a higher average blood fat than any other group of infants in the series studied. Infants fed on milk mixtures containing no fat showed a low blood fat percentage, much lower than those being completely starved. Some of the infants being starved were suffering from "intoxication" and a few developed acidosis. The infants with acidosis showed blood fat percentages essentially the same as those who did not have acidosis. The fact that certain groups of infants showed amounts of blood fat that differed distinctly from the general average of other groups, suggested the desirability of further work on special types of nutritional disorders. It would be of especial interest to study further the particular group of cases in which failure to thrive had been attributed to difficulties in the digestion and absorption of fats.

The Relative Efficiency of the Different Mercurial Preparations in the Treatment of Congenital Syphilis in Infants and Children as Determined by a Quantitative Analysis of the Mercury Eliminated in the Urine.—Dr. WALTER REEVE RAMSEY of St. Paul, Minn., presented this communication, in which he said that up to the present time the form, dose, and method of administration of mercury in the treatment of syphilis in infants and children had been more or less haphazard. The series of experiments discussed were undertaken to determine, if possible, the extent of the absorption of mercury into the circulation as indicated by the elimination in the urine, when the ordinary methods and dosage were employed, and the time during which the mercury continued to be eliminated in the urine after the mercury had been discontinued. From the series of experiments shown in the charts which were presented the following conclusions were drawn: In infants and children, mercury, when given by the mouth, by inunction, or subcutaneously, was excreted at least partly by the urine. In the new born infants and older children, mercurial ointment when placed in contact with the skin, without any friction being used, protected and sealed by waxed paper from being volatilized and inhaled, was taken up by the skin and eliminated in the urine, and continued to be excreted in the urine for some time after all treatment had been discontinued. By inunction, mercury was readily taken up by the skin and eliminated in the urine, and continued to be eliminated for a considerable length of time. When one inunction was given, the maximum daily amount of mercury was usually eliminated during the following twenty-four hours, smaller amounts being eliminated for varying lengths of time. Where continuous inunctions were given there was an accumulation in the system and considerable amounts were eliminated at intervals with only traces between. It was therefore probable that it was unnecessary to have mercury in contact with the skin either with or without rubbing as often or as long as had been generally thought necessary. This, however, must be determined by further clinical investigation. Mercury salicylate suspended in oil and given subcutaneously continued to be eliminated in the urine in appreciable amounts for as long as eight days, the daily amounts eliminated varying widely. It was therefore probable that repetition of the treatment not oftener than at intervals of eight days would be sufficient. Mercuric chloride by the subcutaneous method continued to be eliminated for ten days. In all cases in which mercurial chloride was used either by mouth or by the subcutaneous method, protein was found in the urine. Calomel one-quarter of a gram every two hours, for four doses, and gray powder one-half a gram continued to be eliminated from the urine in appreciable amounts for as long as nine days, the maximum amount being eliminated during the twenty-four hours following the administration. It was therefore probable that the daily use of any of the mercurial salts in the amounts usually prescribed was unnecessary and presumably harmful. The investigations would be continued with the idea that some degree of accuracy would be attained in the treatment of syphilis by the different mercurial preparations.

Dr. HOWARD C. CARPENTER of Philadelphia asked if the calomel ointment was recommended instead of the official blue ointment which was formerly used. He said that some work done by Dr. Kolmer led one to think that the calomel ointment was more readily absorbed than the blue ointment, and in that case it should be used as it did not have the disagreeable features of the ordinary blue ointment.

Dr. RAMSEY replied that they had determined that the calomel ointment was as readily absorbed as the blue ointment. The toxicity of these preparations had not yet been determined, but he hoped to be able to say something about that next year.

Standards for Growth and Nutrition of School Children.—Dr. L. EMMETT HOLT of New York presented this communication and showed charts giving the weight curves from observations upon over 50,000 boys of different nationalities both in this country and abroad. He stated that the weight-to-age variations were so wide as to make this relationship of very little value when taken alone. The normal variations in the weight of healthy children of the same race were from 10 to 15 pounds between the sixth and the tenth year, while from the tenth to the sixteenth year the range is from 20 to 40 pounds. In a private school in New York for boys who came from the wealthiest homes the weight range from the twelfth to the sixteenth year was from 40 to 50 pounds, all weights being taken without clothes and by the same physician. The height-to-age variations were still less significant. Height was even more influenced by race and family inheritance than the weight. Children of the well-to-do classes exceeded those of the less favored in height much more than they did in weight. The relation of height-to-weight was the only one which was really important as indicating the state of nutrition; but here also considerable variations existed in healthy children. A child's nutrition might be considered below the normal when he was ten per cent. below weight for his height between the sixth and the tenth year, or twelve per cent. below from the eleventh to the sixteenth year. The best of all guides to the state of nutrition, and more important than either of the

foregoing, was the annual rate of increase in weight and height. The annual increase in weight was from 4 to 6 pounds a year from the sixth to the tenth year; while it rose to an average of 13 pounds in the fifteenth year. Girls gain at the same rate as boys up to the age of ten years, but surpassed them for the next three years. The annual increase in height varied normally less than the weight. The average increase was from 1¾ to 2 inches a year from the sixth to the eleventh year; it rose to its highest point in boys from the thirteenth to the sixteenth year when it was usually 2.5 to 3.0 inches a year. In girls it was highest from the tenth to the fourteenth year. As a rule growth in height and weight were in healthy children along parallel lines. On insufficient food, growth in height might go on though there was loss in weight. Observations upon 1243 school boys between ten and sixteen years showed that they increased in weight 1¼ pounds more in the six months from May to November than from November to May, and that the gain in height was 0.38 inches more during the first named period.

Dr. Fritz B. Talbot of Boston said he was interested in these figures because they had need of them in the work they were doing at the Carnegie Laboratory at the present time. In their work in metabolism they had been able to establish a ratio between the metabolism and the body weight, and he should not be much surprised if there was some such relation between weight and height as they had found between weight and metabolism. The figures which Dr. Holt had presented were very important to those who were working with children between the ages of two and twelve years.

Dr. Godfrey R. Pisek of New York said they had need of just such an estimate as Dr. Holt had given them. Many of the observations made in reference to weight and height were unscientific, but when the figures were made by members of this society or under their supervision they could be depended upon.

Dr. John Lovett Morse of Boston called attention to the fact that some observations with reference to the rapidity of growth showed that growth in height was most rapid in the spring and gain in weight was most rapid in the autumn. Dr. Holt's figures showed that growth in height was most rapid in the summer.

Dr. J. P. Crozer Griffith of Philadelphia spoke of the need of making allowance for the weight of clothing. The younger children were weighed without clothing and the older children with clothing. This allowance should be made and was made in Bowditch's figures. Dr. Griffith recalled that he had made observations on 200 children between the ages of two and six years and that all of these children were weighed undressed.

Dr. Alfred F. Hess of New York said that during the past six or seven years he had been following the weights and heights in children that were not tuberculous but merely undernourished. It had been his experience that they did not gain well in the summer months. He thought that the reason Dr. Holt found the gain greater during the summer months was because these school boys were housed up in the winter and led an outdoor life in the summer. Observations to be of practical value should be made on hundreds of thousands of children.

Dr. Charles Hendee Smith of New York said that in connection with their work in the nutritional classes at the Bellevue Out-patient Department, the had plotted the curves of a large number of children. They found that a large number of the city children ran under the average as estimated by Bowditch. Undernutrition affected growth in height as well as weight. These children could be made to grow in height as well as to increase in weight by careful feeding. Heredity was also a factor. The children of taller parents if treated properly could be made to grow more rapidly than those whose parents were shorter.

Dr. Godfrey R. Pisek of New York stated that anthropologists had agreed to throw out gross variations in plotting curves, and this was a point to be taken into consideration in this work also.

Dr. Holt emphasized that the normal curve was not a line but a zone, and a much wider zone that they had hitherto appreciated. With reference to the weight of the clothes of which Dr. Griffith had spoken, it might be recalled that Bowditch had shown that the weight of the clothes in boys and girls averaged very closely to the same figures. Dr. Hess was perhaps right in thinking that it was the out-door life during the summer months that accounted for the more rapid growth during that period. In studying the records of the individual boys the gain in weight and height was almost symmetrical, unless there was a sickness which sometimes made a difference. Dr. Holt stated that in his opinion the Dunfermline scale was not a good standard. Under Dr. Baker's supervision, 170,000 New York school children had been examined according to this scale and results were reached which were quite at variance with the truth.

The Complement Fixation Test for Tuberculosis in Infancy.—Dr. Henry Heiman of New York read this paper in which he gave the results of the complement fixation test in a series of 59 patients whose ages varied from the six months to twelve years. Of these 16 cases were tuberculous, six probable or suspicious, and 23 were non-tuberculous. Among the former group were six cases of tuberculous meningitis. Complement fixation reactions on the blood of these patients with both antigens was negative in four and suspicious in two cases. Of seven cases of pleural effusion, one was definitely tuberculous, three were probably tuberculous, and in three others the etiology could not be determined. In these cases the complement fixation tests were negative with both antigens. The serum of the three patients in whom the etiology was not definitely determined gave negative reactions also. Of six children with pulmonary involvement, two being cases of miliary tuberculosis with the usual course, all gave negative reactions with both antigens. The diagnosis was subsequently confirmed by findings at the autopsy table. Among 28 cases with no signs or symptoms of tuberculosis infection, complement fixation tests revealed three strongly positive reactions, one faint inhibition, and one suspicious reaction. In view of the very favorable results reported by other men with the same antigens in general groups of individuals, before discarding the test it was desirable that they should learn the experience of others in this field.

Dr. Paul Armand-Delille of France said that some years ago he had made complement fixation tests in tuberculous children and adults, using old tuberculin and other antigens, and he had found exactly what Dr. Heiman had found. He found that in differentiating the tuberculous from the non-tuberculous the complement fixation test was of no value.

Dr. J. P. Sedgwick of Minneapolis said he thought that the results with the complement fixation test in tuberculosis depended largely upon the antigen. Dr. Larsen of the University of Minnesota had an antigen that gave more reliable results than those that were being used. We should not discard the complement fixation test until Dr. Larsen reported on this work.

Dr. Heiman said he wished to agree with Dr. Sedgewick. We were not going to discard the complement fixation test for tuberculosis but we were going to look for a further improvement in the technique.

Twenty-six Cases of Pyloric Stenosis in Private Practice, with Operation by the Rammstedt Method.—Dr. Charles Gilmore Kerley of New York presented this paper. He stated that of these twenty-six cases, twenty-four had been operated on by Dr. Downes at the Babies' Hospital, one by Dr. Downes at St. Luke's, and one by Dr. Jennings at the Brooklyn Hospital. Of these cases seventeen were boys and nine girls. The lowest weight at operation was 4 pounds 2 ounces; the birth weight of this child was 5 pounds 8 ounces. This patient made an uneventful recovery. Vomiting began at birth in one instance, at two weeks or under in eleven cases, between two and four weeks in thirteen cases, at six weeks in one and at eight weeks in one. The onset was abrupt in all but one. Twenty-three were entirely breast fed at the onset of vomiting. The vomiting in all cases was projectile, the stools and urine were very scant in all, and in all there was a steady loss of weight after the onset of the vomiting. The peristaltic wave was present in all cases. There was no rise in temperature. A tumor was palpable in all but one case, and was most frequently located above and to the right of the umbilicus. Postoperative observations showed no postoperative vomiting in seventeen cases, nine vomited post-

operatively, but all of these recovered. Postoperative temperature above 101° F. was noted in seven. Four cases ended fatally, a mortality of 15.3 per cent. In three of these the children had vomited for weeks and were in wretched condition at the time of operation. The fourth child had vomited for weeks, but was in fairly good condition. Immediate operation was advised, but the family insisted that the child be kept under observation for a few weeks. The child developed an acute gastrointestinal infection and in three days the operative risk had risen 50 per cent., and the child died in collapse three hours after the operation. The postoperative management carried on at the Babies' Hospital was that evolved by Dr. Holt, which consisted in wrapping the child in a warm blanket when it came out of the operating room, and when it was put to bed surrounding it with hot water bottles outside the blanket. For an hour or two after the operation the head of the bed was kept lowered to prevent the aspiration of mucus into the larynx; this was absolutely necessary. Ten or twelve hours later the patient was put in the semi-erect position, which prevented the regurgitation of food and permitted the easier escape of gas. As soon as the patient was placed in bed hypodermoclysis of 120 c.c. of saline solution was given, and if the condition was very poor a hypodermic of 5 minims of adrenalin, 1-1000, was administered and repeated every four to five hours. Dilute whisky every few hours for the first five or six days had proven of great value. Transfusion in a few cases that had collapsed had been of material benefit. One and one-half hours after the operation 10 c.c. of water was given, and an hour and a half later 10 c.c. of barley water and breast milk. Two hours later 8 c.c. of breast milk was given, and then every three hours alternated with water and gradually increased in amount, so that at the end of forty-eight hours about 30 c.c. was given at a feeding, with 4 c.c. of barley water. The barley water was then discontinued and the breast milk increased, so that by the eighth day following operation the baby was taking 60 c.c. at each feeding. By the eleventh or twelfth day the baby was nursing entirely. In well nourished babies a sponge bath was given daily; in emaciated children an oil rub was preferable. A teaspoonful of castor oil was usually given twenty-four hours after the operation if there had been no stool. If there were more than three or four stools a day, protein milk should be substituted for three or four breast feedings. The wound was not disturbed for four or five days unless some indication arose. The stitches were removed on the ninth or tenth day. A low mortality in these cases depended upon early diagnosis and immediate operation. The presence of a palpable tumor demanded prompt surgical interference. Operation by a competent surgeon, using the Rammstedt method, which meant a rapid operation, would insure a mortality of about 5 per cent. in cases that had not vomited more than two weeks. Sudden and unexpected death in the palliatively treated cases was not uncommon. Acidosis due to defective urinary secretion with retention of acid was an ever present danger.

Dr. L. Emmett Holt of New York stated that at the Babies' Hospital they had had some two hundred cases of hypertrophic stenosis of the pylorus, and that did not mean that every baby that came to the hospital had hypertrophic stenosis of the pylorus, for in most of these cases the diagnosis was made outside the hospital. The more he studied the matter the more he became convinced that the treatment of this condition was operative. In about 100 cases in which the vomiting had lasted less than four weeks the mortality was 40 per cent., while in those in whom the vomiting had lasted over four weeks the mortality was 50 per cent., which showed very clearly that the chances for life were better if the operation were performed early. While the risk of operation was something to be considered, the risk of not operating was greater than the risk of operation. If the operation was performed as Dr. Downes did it, it took only ten to fifteen minutes. Hemorrhage occurred in very few cases. In their last fifty or seventy-five cases there had not been a serious complication. They began giving food, a teaspoonful, immediately after the child came out of the anesthetic. To withhold food for twenty-four to thirty-six hours after the operation was to diminish whatever chances of recovery the child had. At the end of a week the child was getting 2 ounces of breast milk, but he was not put on the breast until nine or ten days after the operation, the reason being that the amount of food must be very carefully measured. There was no question that the after treatment presented great difficulties.

Dr. John Howland of Baltimore said that while he did not wish to advise any special method of treatment, he thought it was possible to cure a great many of these cases without operation. Patients with hypertrophic stenosis of the pylorus could not be cared for at home and they could not be treated by operation without breast milk. Operation did not stop vomiting in all cases. He had had cases that vomited almost as badly after operation, as though they were being treated medically without operation. The spasm was the factor that was important. He had had one child with great peristaltic waves and a palpable tumor of almost artilaginous consistency at the time of the spasm, yet in this case there was no great amount of thickening. To have immediate recourse to operation because there were peristaltic waves and a tumor was most unwise.

Dr. Alfred F. Hess of New York said he agreed with Dr. Howland that operation was not always necessary in these cases of hypertrophic pyloric stenosis. The operation had been so simplified that the tendency was to operate too frequently. The question of prognosis was not how long the baby had vomited, but it was a question of the operator. He had seen Dr. Downes operate and it gave one the impression that the operation was a very simple matter. That was wrong; it took a very skillful man to perform this operation and get good results. Spasm and active peristalsis did not necessarily mean that hypertrophy was present. A catheter could frequently be passed through a pylorus where there was active peristalsis; even where there was a tumor one might be able to get the catheter through.

Dr. Henry Dwight Chapin cited one instance in which the Rammstedt operation was performed and the child died within forty-eight hours. At autopsy it was found that the food had gone through into the peritonesal cavity. The surgeon had gone a little too far and cut through the mucous membrane.

Dr. Henry Heiman of New York expressed the opinion that every case of this kind should be treated on its own merits. To place dependence on the length of time that vomiting had lasted was not so important as to watch the feces. The condition of the feces was more important than the number of pylorospasms the child was having in twenty-four hours.

Dr. Walter R. Ramsey of St. Paul said that progressive and continuous loss of weight in these cases was always an indication for operation.

Dr. Henry F. Helmholz reported his experience with fourteen cases of pyloric stenosis treated with thick cereal gruels. These cases occurred in nervous children and all showed the typical symptoms of pyloric stenosis, with inability to retain food or even plain water. All recovered under this treatment except one; that child was operated on and recovered also.

Dr. H. M. McClanahan of Omaha related his experience with 14 cases of this condition. He said that its mortality was higher than that given by Dr. Kerley, but that nine of the fourteen cases recovered. The surgeon who did his operating succeeded in getting better results each year, and completed the operation more quickly by the old fashioned method. Exposure of the bowels in operating was a large factor in influencing the mortality. It was quite possible to have a pylorospasm without stenosis and these cases would naturally get well without operation.

Dr. J. P. Crozer Griffith of Philadelphia said that he used to talk a great deal about treating these cases medically, but he had undergone a change of heart. He had had cause to regret delaying operation, but he had not had any cause to regret operation. He now favored operation more frequently than formerly.

Dr. John Lovett Morse of Boston expressed himself as very much surprised at the difference of opinion in regard to hypertrophic stenosis of the pylorus. When one found, months after a gastroenterostomy had been performed, that hypertrophy and stenosis were still

present, it was difficult to understand how any one could believe that medical treatment would be effective in such a case. He still believed that there were two types of cases, the one a real hypertrophic stenosis, and the other a spasm of the pylorus, and there was a small third class of cases in which there was a spasm added to some hypertrophy. It seemed to him that the Rammstedt operation was the operation to do. It required a good surgeon and then the child could be off the table in ten minutes.

Dr. Oscar M. Schloss of New York suggested the possibility that with the diminished intake of fluid and the lessened secretion of urine an acidosis might result, which might have a deleterious effect in case of operation.

Dr. Godfrey R. Pisek of New York advised giving a sinus injection of saline before operation. He thought there was but one side to this question. He also had a record of not wishing to have cases operated on, but now when he saw a case in which the diagnosis was definitely made he wanted it operated on as soon as possible.

Dr. D. M. Cowie said that he thought in stenosis of the pylorus of large caliber medical treatment might be effective, and if the children could be carried along in this way as they grew and the stomach enlarged the pylorus and the caliber of the stenosis also enlarged. The case should be examined carefully to determine whether one was dealing with a large or a small caliber stenosis and then the treatment should be influenced by the condition found.

Dr. Kerley, in closing, said that most of the cases in this series had been seen by other physicians before he saw them and had been treated by various palliative measures. They were not cases of spasm alone; there was no question that they were cases of stenosis. He had passed through all the stages of palliative, non-operative treatments, and waiting to see what would happen, and he had seen the children die. All that was required to make a diagnosis of pyloric stenosis was a well marked palpable tumor; those who would not accept that as a diagnostic sign now would do so in a few years when they had seen a few more cases.

A Preliminary Report upon the Value of Auxohormones and Other Agents in the Feeding of the Young.—Dr. E. W. Saunders of St. Louis presented this communication, in which he called attention to a class of patients in which the clinical course was somewhat as follows: A baby that had previously given no cause for anxiety was suddenly taken ill, the symptoms being insomnia, frantic nervousness, vomiting, loathing for the particular kind of food upon which it had been fed, rapid pulse, and convulsions of a mild type. There would be slight fever and no acetone breath. Rarely tetany was manifested in the hands or feet but without facial involvement. Death came often without further sign. In studying the etiology of these cases there was one factor invariably found, namely, a history of prolonged subsistence upon dead food exclusively. There was a class of fat rickety cases, due most often to a certain tinned food, another class, a fulminating type of Barlow's disease, due to another brand, and of the writer's cases nine-tenths were found to have been subsisting for months on a third variety of these foods. Attempts had been made to identify the syndrome with Finkelstein's sugar intoxication, with thymic asthma, or tetanus, or the spurious hydrocephalus of Marshall Hall, but it did not fit in with the picture of any of these conditions. In the treatment much might be hoped from the prompt and vigorous employment of large doses of glonoin dropped on the tongue and exclusive tube feeding, using a live rennet whey containing a rapidly increasing amount of unsterilized cream, autolyzed yeast, and green vegetable juices. In extreme cases a hypodermic of morphine or atropine was given, but ordinarily a fractional dose of veronal acted as a sedative. Calcium bromide and the phosphates seemed to be beneficial in all cases. Hypodermoclysis or injection into the longitudinal sinus was warranted in the severer cases. In prescribing food for the baby we thought in terms of percentages, we allowed a per diem of calories, we guarded against infection, but all would be in vain if we did not secure the presence and undiminished power of the mysterious food hormones, the vitamines. Yolk of egg in emulsion ranked next in fat and hormone value when milk was not obtainable. Honey, by which a child would often profit more than by purified sugar, and vinegar, which the essayist had used for several years past with increasing satisfaction, and which authorities said enhanced the value of vitamines, were all valuable agents. Gruels of natural grains, ground whole, had proved far more acceptable than one per cent. decoctions of devitalized grains. Young babies tolerated six per cent. gruels well, and such an amount of cereal augmented the mineral content of the formula greatly. A baby's milk might perhaps be constructed out of an ounce or more of cocoanut oil, emulsified with a natural six per cent. gruel which had been boiled with cabbage, and sweetened with honey. According to McCallum, the green vegetable juices had the power to hormonize the inert fat and raise it to the rank of a glandular fat in promoting growth. Many infant foods were destitute of vitamines and glandular fat and of an adequate mineral content, and called for governmental supervision in the interest of the children. Some years ago in response to a letter of inquiry the speaker recommended this course to the Department of Chemistry, and now Dr. Alsberg, the Chief, was willing to meet a committee of the society with a view to formulating a bill for introduction to Congress requiring a label on all patent foods showing whether they contained hormones or not. Every parent should be taught the value of green vegetables.

The Appeal of the American Reserve Corps to the Members of the American Pediatric Society.—Major Channing Frothingham, Jr., made this address. He said that the Government needed medical men and the community needed medical men. The question was where was the dividing line to be drawn. Many men who were specialists wondered if there was any room for them. If the obstetrician or the pediatrician had asked him a year ago whether there was a place in the army for him, his answer would have been "No," but at that time he was examining recruits on part time. Since that time he had had experience at Fort Benjamin Harrison and had learned that there was a great deal to do in the Medical Department of the Army which had nothing to do with the profession itself. He wished to say that it was quite worth while going into the army to do things that were not professional in the strict sense of the word. At the present time the Medical Department of the Army was standing the strain of a terrific expansion and was standing it well. There were few physicians in the army who had not specialized before entering the service. A man might do something for which he was not trained and might learn to do it well. To show what the medical officer did in the army the speaker began at the front line and described the way in which the wounded soldier was cared for from the time he reached the first dressing station until he was established in a base hospital. Even in the front line an out-patient department was run and the regimental physician got a few patients every day. From the first dressing station to the field hospital and from the field hospital to the base hospital the transportation was under the supervision of medical men. Much of this work the pediatrician could do as well as anyone else. This did not mean that all the pediatricians would be pushed into the front line. In the evacuation hospital, there had to be a medical man as well as a surgeon at the head. In the special hospitals conducted in connection with each large hospital, there were specialists for the eye, for head injuries, for nervous troubles, etc. A big base hospital was similar to a large civilian hospital and should be run on exactly the same lines. The problems of the base hospital were those of acute infection. They were the problems of the contagious diseases of childhood and these were the diseases that the pediatrician was accustomed to care for. At the cantonments they had chest examiners and heart examiners and in this work pediatricians would be perfectly capable. How were they to be fitted into the niche? If the Government did not need them he would advise them to put their names down with the Red Cross. There was another side which was worth mentioning. In the first place it was great fun to be in the game and to be taking part in this big scheme of organization and to be doing what everyone thought was the proper thing to do. If

one did not go because he felt it his duty, he should go because it was a splendid way to improve his medical knowledge. This would be found particularly true of the acute infectious diseases. They would not see these in private practice to the extent that they would see them in the army. The army offered a splendid opportunity for the study of this class of diseases. In closing, Major Frothingham said: "It is a big game and all men must get into it. You must come in, for your Government says it needs you."

A Case of Erosion of Blood Vessels in the Course of Scarlet Fever.—Dr. JOHN HOWLAND of Baltimore reported this case, which occurred in a child 5½ years of age. The child became ill on December 1, 1917, and two days later a membrane appeared on the tonsils. The child developed no characteristic eruption and the case was diagnosed as one of diphtheria. Subsequently, albumin was found in the urine and it was thought that the child had a post-diphtheritic nephritis. Twenty-three days after the onset the child became very ill. There was found to be a necrosis of the right tonsil with a very foul secretion and a characteristic scarlet fever desquamation. There was a mass in the right side of the neck which was opened and about two ounces of pus evacuated, but no blood. In the middle of the night the child was found exsanguinated and in a pool of blood. The child was given 300 c.c. of salt solution subcutaneously and transfused with the mother's blood, 250 c.c. being given intravenously. The child was given morphine and an attempt made to examine the abscess cavity, when there was a gush of blood, apparently from the external carotid or the lingual. The vessels were ligated and the hemorrhage controlled. Another transfusion was given and after that the child improved until two weeks later, when another hemorrhage occurred as the result of the soughing of a suture on the external carotid. After this the child improved quite rapidly and eventually recovered, though convalescence was complicated by a psychosis. Hemorrhage after scarlet fever was reported in about 50 cases, but in most instances it was from the internal jugular, and such cases ended fatally.

Dr. HOWARD C. CARPENTER of Philadelphia cited a somewhat similar case, in which, during a cervical adenitis that seemed to be progressing favorably, a hemorrhage, apparently from the carotid, occurred and the child died within two minutes.

A Case of Hirschsprung's Disease.—Dr. WALTER LESTER CARR of New York reported this case, occurring in a girl six years of age. She gave a history of constipation for five years and of vomiting for the last twenty-four hours. She was in a condition of shock at the time of admission to the City Hospital. The temperature was 97.5°, pulse 120. The abdomen was greatly distended and there was a constant involuntary discharge of feces. Colonic irrigations of saline solution were given with stimulation, heat, etc. A partial blood count showed 5,100,000 red cells and 11,300 white cells. The blood was viscid and was not absorbed by Tallquist paper. The child died 11 hours after admission. A partial necropsy disclosed a marked distension of the intestines which was particularly evident in the sigmoid colon which was bent upon itself. The wall of the upper part of the rectum and the lower part of the sigmoid colon was slightly calcified and the lining mucous membrane was very granular. There was hyperplasia of the mesenteric lymph nodes. The anatomical diagnosis was idiopathic dilatation of the sigmoid colon. Hirschsprung's disease, with secondary calcification of the lower part of the sigmoid and the upper part of the rectum. A microscopic examination of the tissue from this specimen showed a complete loss of mucous membrane, and in its place was a vascularized round celled proliferation of the submucosa. There was a corresponding hypertrophy of the inner and outer muscular coats as shown by the microscopic slides.

Dr. HENRY KOPLIK of New York said that sometimes these obstructions were alleviated by nature, by diet, and by enemata, and sometimes they went on to obstruction, were operated on, and passed away. The prognosis was very bad if one made an artificial anus. Some of the cases with this condition went on to adolescence. He had published such a case fourteen years ago, in which the condition continued until adolescence and the boy then passed away from obstruction. The condition might be rapidly fatal or it might go along quite normally for a time.

Dr. JOHN HOWLAND of Baltimore said that a point not brought out was the different types of the condition. There were instances in which there was not only hypertrophy and dilatation, but in which the bowel was extremely long. In some cases there was no dilatation so far as the *x*-ray showed and in others there would be great dilatation and hypertrophy. The point to be made was that the treatment and prognosis depended upon the type of the disease.

Dr. FRITZ B. TALBOT of Boston said that the name Hirschsprung's disease was applied to a stage in a common condition. When this condition was dignified by the name Hirschsprung's disease it was in a late stage of the disease. The time to treat the condition was before the dilatation had occurred. There were many cases of Hirschsprung's disease walking about to-day, some would reach the stage of dilatation when they would be recognized and others would not.

Dr. CHARLES GILMORE KERLEY recalled that he had reported 20 cases of elongated sigmoid and showed the *x*-ray plates before the Detroit meeting of the American Medical Association. He felt that these cases were fairly usual and that the name Hirschsprung's disease should be dropped. They were identical with the elongated sigmoids that folded upon themselves and became sacculated and dilated and that were accompanied by sacculation and later constriction. The condition was one that was very frequent and it was the severe cases that went on to the formation of gross lesions.

Dr. HENRY HEIMAN of New York said that the first stage of this condition was what was known as megacolon to which he had called attention many years ago. The first stage was megacolon and constipation and later it was Hirschsprung's disease and obstruction.

Dr. LANGLEY PORTER took issue with the last statement, and said that congenital megacolon was found at birth and in the premature child. He had placed on record a number of such cases.

Dr. HENRY KOPLIK of New York said that Hirschsprung thoroughly described the condition as congenital or an anomaly. He had specimens also showing that the condition might be congenital.

Dr. CHARLES HUNTER DUNN of Boston agreed with Dr. Koplik and Dr. Porter that the condition might be congenital. He cited two cases which he had seen in the first week of life, in which the condition could not have been produced by prolonged constipation and must have been congenital.

Dr. TALBOT of Boston said that if they would think back he had spoken of a condition and not a disease. If they would look over the diagnoses in the hospital records they would find that the condition was called Hirschsprung's disease irrespective of whether it was congenital or acquired. The point he wished to bring out was that there was a condition which developed into Hirschsprung's disease and which could be prevented from so developing by appropriate measures.

A Case of Cardiospasm Followed by Hypertrophy, Dilatation and Stricture of the Esophagus, Treated by Gastrostomy, and Subsequent Dilatation of the Esophageal Stricture.—Dr. EDWIN E. GRAHAM of Philadelphia reported this case. He stated that clinically the element of spasm was unquestionably present, the food entering the stomach very much better at some times than at others. The diagnosis of stricture of the esophagus was verified by the *x*-ray plates. A point of particular interest was that the diagnosis of ulcerative esophagitis was made by direct inspection with the eye, the esophagoscope having been passed by Dr. Chevalier Jackson, and the ulcerative area having been clearly seen. The treatment consisted in gastrostomy, feeding the child through a tube for several weeks, nothing being allowed by mouth except small quantities of water, and finally dilatation of the stricture of the esophagus by sight and not by touch. The esophagoscope was passed and then Dr. Jackson passed bougies, small delicate ones at first and then larger ones. There was a second child in the Jefferson Hospital with a stricture of the esophagus caused by swallowing lye who was being treated in the same way.

A Brief Report of a Case of Congenital Stricture of the Duodenum; Operation, Death.—Dr. H. M. MCCLANA-

HAN of Omaha said that this baby gave a history of vomiting from the third day after birth. There was intermittent loss of weight and the stools increased in frequency and became green in color at times. The Roentgen plates revealed a large shadow over the stomach, but a distinct shadow down to the colon, showing that the pylorus was pervious. At no time were there any peristaltic waves nor was a mass palpable at any time. When the child was a month old the parents gave their consent to operation. Through a medium incision the stomach crowded itself out of the abdomen on account of its great distension. The pylorus was moderately constricted by a distinct circular induration, but not sufficiently to account for the great distension. The duodenum was greatly distended and, following this down to the point where it passed through the transverse colon, a very marked constriction was encountered. It was found that all the distension was above the mesocolon. On examining the opening into the mesenterium a constricting band was found compressing the duodenum 8 inches beyond the pylorus. The band belonged to the mesenterium and not to the intestine. The band was divided and the distension of the duodenum relieved at once. A posterior gastroenterostomy was performed on account of the distinct pyloric constriction and the probability of a recurrence of the condition in the fossa of Treitz. The child died very suddenly in the night, following the operation. The fact that at times the stools and gain in weight were normal indicated that the band did not entirely constrict the duodenum all the time.

Dr. FRITZ B. TALBOT of Boston related the history of a somewhat similar case, in which there was a constricting band over the duodenum. An interesting point in this case was the obstructive vomiting for only a part of the time. This child spent most of its time in the knee-chest position, and when in that position did not vomit. The band over the duodenum was relaxed by that position so that the food could pass through.

Dr. LANGLEY PORTER of San Francisco also reported two somewhat similar cases, one coming to autopsy and the other to operation.

Dr. L. E. LA FETRA of New York said he had seen one of these cases during life and another at autopsy, and the symptoms were very much like those of hypertrophic pyloric stenosis.

A Case of Balantidium Coli.—Dr. L. R. DEBUYS of New Orleans reported this case. He described the organism, reviewed the literature on the subject, the pathology, symptomatology, diagnosis, prophylaxis, and treatment. He stated that the infection was a rare one in man, less than 150 cases having been reported. The infection was exceedingly rare in children, there being only three instances on record. The writer's patient was five years of age and had helped rounding up the pigs, at times eating his food in the pig pens. He had been ill for nearly a year with diarrhea. During this time there had been periods of improvement, though each attack was more pronounced than the preceding one. The stools resembled those of amebic dysentery, containing blood and mucus. The rectal tube was passed and the organism was found. The patient was poorly nourished and had a catarrhal stomatitis, otherwise the physical examination was negative, except for some pain in the lower abdomen. In the treatment of this infection ipecac or its alkaloid emetine seemed to be indicated, because of the resemblance of this infection to that of amebic dysentery: (1) In the location and invasion of the organisms in the tissues; (2) in the histological pathology; and (3) in its clinical manifestations. It was hardly to be expected that local flushings would be of any avail after the infection was established.

A Case of "Cribbing" in a Young Infant; Dilated Stomach; Spasm of Diaphragm.—Dr. PERCIVAL J. EATON of Pittsburgh reported this case. He stated that the child was apparently normal at birth, weighing 9 pounds 7½ ounces, and was breast fed for three weeks, but had had during the third week supplementary feeding of cream mixture and then condensed milk. He sucked fists, tongue, and nipple, and had lost weight. The stomach was dilated, the lower edge of the greater curvature reaching about three-quarters of an inch below the line of the umbilicus. The wave motion was visible and somewhat exaggerated. There was much tympany of the stomach and little of the intestine. The baby was placed on a raw milk formula at regular and absolutely fixed intervals, and his arms were splinted to keep his hands from his mouth. The child was also postured to get the aid of gravity in keeping the fluid contents of the stomach at the pyloric end. Massage of the stomach was persisted in. At the time of the greatest activity of the vomiting there was a distinct spasm of the diaphragm. The vomiting was of the projectile type. This child's sister, now three years old, was also a cribber. An occasional dose of strontium bromide was given the child, and also phosphorated oil in cod-liver oil. The child also had an abundance of fresh air and sunlight.

Dr. CHARLES HERRMAN of New York recommended the use of atropine in cases of this kind. He and his colleague had used atropine in these cases and the results were sometimes favorable.

Dr. D. M. COWIE of Ann Arbor said that one method of treatment of cribbing was to tie a spool in the mouth. By this means one could break the child of the habit in a couple of weeks.

Dr. SAMUEL S. ADAMS of Washington asked why this was called cribbing.

Dr. EATON replied that he had used that term because the child bit and chewed on anything that came near him, just as a horse bit and chewed its stall. The child was responding well to treatment.

A Case of Kala Azar.—Dr. FRITZ B. TALBOT of Boston reported this case, which occurred in a child born in Greece. Infection presumably occurred before the child came to this country. This was the first case of kala azar reported in this country, so far as the writer was able to ascertain. The history of the case showed the characteristic onset. The symptoms were pallor, weakness, and enlargement of the abdomen. The spleen was removed and the diagnosis made from a smear of the spleen pulp. The secretion was later obtained from the inguinal glands and also showed a positive culture. Various forms of treatment were tried without avail. The course of the disease was apparently benefited by splenectomy. Later there was a relapse. At this time atoxyl was used without any effect. Tartar emetic in 2 per cent. solution was used in doses starting with 1 c.c. and working up to 4 c.c. This eventually caused the symptoms of salivation and was therefore discontinued. From that time forward the child improved rapidly and had remained normal ever since. It was seen one year after it left the hospital, when it was normal in every respect.

Dr. ALFRED F. HESS asked if the diagnosis could be made in any other way than by smears from the spleen.

Dr. CHARLES HERRMAN of New York asked if one could not puncture the spleen and obtain a smear in that way for diagnostic purposes.

Dr. TALBOT said that attempts made to culture the organism from the blood had been almost universally unsuccessful. One could easily remove an inguinal gland, and one with experience could culture the organism from that without difficulty. In the tropics they punctured the spleen and obtained a smear for culture.

A Case of Intussusception.—Dr. FRANK X. WALLS of Chicago presented this report, which he said recorded an observation made in the fluoroscopic examination of the lower bowel which revealed a picture of great diagnostic value that had not thus far been brought out in the literature of intussusception. In a boy, with the symptoms of intussusception, physical examination showed a soft tumor mass about 2 by 3 inches in extent in the upper right quadrant of the abdomen, with its long axis transverse. The fluoroscopic examination, after the injection of a barium buttermilk enema from the height of 18 inches, showed the barium entering the bowel, filling it from below upward, until the mass reached the middle of the transverse colon. Here the column of barium halted a moment and then a small stream of barium trickled from the heavy column along the periphery of the colon for a distance of about an inch, and after this the column did not advance or alter its position. The arrested barium then looked like a solid mass with a decided concave U-shaped termination. The boy was operated on immediately and an ileocolic intussusception about 3 inches long was found, which was reduced. A long appendix that was engaged in the tumor was removed. A prompt recovery fol-

lowed. The wet specimen illustrated the loose approximation between the external and middle layer of the intussusception. If the barium enema was observed under the screen in a case of intussusception the mass would be seen filling up the bowel until it was arrested by the intussusception, and a small amount of the mass would pass for a longer or shorter distance between the intussusceptum and the intussuscipiens. The shadow made by the thin layer would be appreciably different from that made by the dense mass, and the end of the column would appear to be concave or U-shaped.

Dr. Langley Porter of San Francisco suggested that it might be a good idea to use the column of barium, and then under the fluoroscope to attempt by manipulation to reduce the intussusception according to the original method of Hirschsprung, before resorting to an operation. So far as he knew this had not been done.

Dr. DeWitt H. Sherman of Buffalo stated that he had shown some pictures at the New York Medical Society meeting the week before and one of these was a subacute intussusception, similar to the one described by Dr. Wall. Operation was refused and a week or ten days after leaving the hospital the child passed a part of the bowel. The child had since progressed normally.

Dr. Alfred F. Hand of Philadelphia said there were those who thought the diagnosis of intussusception easy, but this was not always the case. He had had a case in a child nineteen months old, showing the symptoms of constipation, colic, and vomiting, which was followed by blood and mucus in the stools. There was board-like rigidity on the lower side of the scrotum. He called in a surgeon, who found a strangulated hernia; this was replaced. Had it not been for the fact that the mass was palpated in this instance, the symptoms would have seemed very much like those of intussusception.

Two Cases of Congenital Cardiac Disease.—Dr. Charles Hunter Dunn of Boston presented this report. He stated that the first case occurred in a baby, two months old, showing the symptom complex of systolic murmur, thrill, and cyanosis. Percussion and the *x*-ray showed no enlargement. Only one ventricular cavity was visible and only one auricular-ventricular orifice. The large vessels opened into this one ventricle. Search was made for the aortic valve which was found above and in the wall of the ventricle. A rudimentary ventricle was found in the wall of this one large ventricle. The second case occurred in a baby three months old, which showed a systomic murmur but no palpable thrill and no evidence of enlargement. Cyanosis was present as shown by the lips, but there was not a proportionate cyanosis of the extremities. No accurate diagnosis was made. On opening the chest an anomaly of the great vessels was discovered, there being a complete transposition of the vessels. The writer recalled that he had presented a case of complete transposition of the great vessels before the Society last year and had described the embryology at that time. In this instance the aorta was divided into two branches and the pulmonary artery into three branches.

Dr. William P. Northrup recalled that forty years ago he had reported a case of transposition of the trunks of the great vessels and said he wished to report a case of patent foramen ovale that he had been able to follow until the girl graduated from high school. She died of a condition not directly associated with her heart anomaly and at autopsy he found a narrowed pulmonary orifice and an incomplete septum ventriculorum. He had done many autopsies in these cases and had always found a narrowed pulmonary orifice associated with the patent foramen ovale. This he had never been able to explain to his entire satisfaction.

Death from Tuberculous Meningitis in a Breast-Fed Infant at Ten Weeks of Age.—Dr. DeWitt H. Sherman of Buffalo presented this report. He stated that tuberculous meningitis in this case was proved by guinea-pig inoculation. This child was normal until its last illness and was never on the street. The family history was negative for tuberculosis, and the child never received any other food than breast milk and a little water which was always boiled. When the writer saw the child, on the third day of its illness, one eye was closed and the pupil of that eye was larger than the pupil of the opposite eye. The pupillary reaction of both eyes was sluggish. There was some bulging of the anterior fontanelle, slight rigidity of the neck, doubtfully exaggerated patellar reflexes, and while the child could be aroused it made no response. All other signs and symptoms of meningitis were wanting, except for slight twitching of the angle of the mouth. The specimen of the spinal fluid stained for tubercle bacilli showed eight bacilli. The morphology of these was that of the human type. The colloidal gold test gave no reaction that was in any way significant. The findings in three guinea pigs injected with the spinal fluid were practically the same, showing extensive tuberculous involvement of the liver, spleen, and abdominal lymph glands. The lungs showed only a few scattered tubercles. These guinea pigs all died in from six to nine weeks after receiving the inoculation.

A Case with Vascular, Joint, Muscle, and Skin Disturbances.—Dr. Richard M. Smith of Boston reported this case which occurred in a child 4½ years of age who gave a negative family and personal history. In November, 1917, she was vaccinated against smallpox, the reaction being violent with high temperature, and involvement of the glands in the groin. A few days after this reaction subsided the child's face became red and swollen and she began to complain of stiffness in bending her knees. These symptoms progressed until all the joints in the body became involved, including those of the spine. The muscles seemed to be in a clonic state of contraction. There were conjunctival hemorrhages and the mucous-membrane of the mouth about the teeth was red, edematous, and in spots hemorrhagic. The skin almost everywhere on the body showed blotchy erythema resembling Raynaud's disease. It also showed a brawny induration and in some portions a slight edema. The lesions of every kind were absolutely symmetrical even to the position of the erythematous blotches on the finger tips. The hair was coarse and abundant. The child before the onset of the symptoms was cheerful and happy, but since the trouble began she had become very tearful, quiet, and did not want to be disturbed. Aside from these things the physical examination was entirely negative. The *x*-ray examination had revealed in the subcutaneous tissues a curious irregular striation unlike anything with which the writer was familiar. The etiology of this condition was extremely doubtful, but he felt inclined to think that the vaccination had nothing whatever to do with it and in this opinion the mother concurred, a fact worth while noting. Possibly some toxic agent had affected the glands of internal secretion. No focus of infection had been found. The skin condition might be primary and everything else secondary to it. The most likely diagnosis seemed to him to be a diffuse scleroderma. Nothing that had thus far been done in the way of treatment had modified the condition in any way. During the last few weeks there had been a slight tendency to improvement.

Dr. Henry Koplik of New York recalled having seen a case exactly like this one in his service at Mount Sinai Hospital. This was one of the rarest conditions met with in pediatrics. Every detail in the case he had seen worked out just as in the case reported by Dr. Smith. No one knew what the diagnosis was. Some thought it a diffuse scleroderma. Finally, Dr. Sara Welt-Kakels saw the patient and said she had seen a similar case before, that it was a neurodermomyositis, which had been described by Oppenheimer. A marked eosinophilia was present. The disease seemed finally to wear itself out and the child became better and able to walk about. The disease as described by the neurologists was not a skin disease, but the skin was affected along with the other structures. In the case to which he had referred they had examined the muscles and found a general atrophy.

Dr. A. H. Beifield of Chicago asked whether these patients had had any itching of the fingers and whether there was any edema of the digital phalanges of the fingers and toes, or any desquamation, and whether there was any alopecia or photophobia. He said he had seen six cases of a similar condition but still more intense.

Dr. Smith, in reply to the questions, said the child had no great amount of itching and no desquamation excepting under the arms and the extreme tips of the fingers and toes. There was no eosinophilia.

Preliminary Report on the Use of Vegetable Milk.—Dr. HENRY DWIGHT CHAPIN and Dr. LUDWIG KAST of New York presented this communication which was read by Dr. Chapin. He said that the milk was prepared from almonds, was pleasant and easy to digest, and seemed worthy of a trial in various nutritional disturbances of early life. The almonds were first finely ground and then covered with water and allowed to stand over night in the ice-box. The following day they were pressed out using a potato, rice, or fruit press, or they might simply be pressed out by hand through four layers of gauze, which was the method usually employed in their laboratory. A comparison was made of the chemical analyses of cow's milk and almond milk which showed that there were certain advantages in the use of the almond milk that might be considered from both a theoretical and a practical standpoint. The almond milk fermented much less easily than ordinary cow's milk; it had a higher fat ratio in the form of almond oil which was sufficiently emulsified to render it easily digestable; the proteins in this milk were much less apt to undergo putrefaction than the casein of cow's milk; almond milk contained a large amount of phosphorus and and a small amount of sodium chloride, which would suggest its favorable employment on such conditions as rickets and nephritis. From its low carbohydrate content it was less likely to cause sugar fermentation. On the practical side it had been tried on more than 1000 adults by Dr. Kast and while some disliked it, actual disturbances had never been caused by it. So far no patients had shown an idiosyncrasy to it. Patients kept on almond milk alone maintained their equilibrium of metabolism and usually gained in weight. It was well taken and served a good purpose in such conditions as nephritis, typhoid fever, intestinal putrefaction, malnutrition, and secondary anemia. It was rich in vitamines. While the authors did not recommend its permanent use they felt that it was desirable and useful as a temporary substitute for cow's milk.

Dr. L. EMMETT HOLT of New York said it seemed to him that Dr. Chapin's vegetable milk might have been useful in diarrhea if he had not added the sugar. Without the addition of the sugar he would have had a mixture with a high fat and high protein and low carbohydrate content.

Dr. OSCAR M. SCHLOSS called attention to the possibility of obtaining a much higher percentage of protein from the almonds than Dr. Chapin had done. The globulin of almonds was much more soluble in a weak alkaline or saline solution than in ordinary tap water.

Transposition of Viscera.—Dr. HOWARD C. CARPENTER of Philadelphia reported this case. He stated that the patient was a seven-months premature infant, whose birth weight was estimated at three pounds. Up to the age of seven years, when he came under the writer's observation, he had had pertussis and measles, and had had hypertrophied tonsils and adenoids removed. Since the age of five years his nutrition had been subnormal. His only symptoms were sweating about the head and a variable appetite. He was a thin, pale, nervous child. After giving the measurements of the child the writer stated that the left side of the chest anteriorly was more prominent than the right. The apex beat was visible in the sixth interspace in the mid-clavicular line. Cardiac dullness extended 7½ cm. to the right of the mid-sternal line and 4 cm. to the left. Cardiac dullness began above in the second interspace. The muscular quality of the first sound was good. A faint, blowing systolic murmur was heard all over the heart area, but loudest at the apex. The pulse averaged 100 to 110, and after exercise was around 140. The abdomen was pendulous, and there was a decided lumbar lordosis. The liver was on the left side, the upper border being at the sixth rib in the left clavicular line and the lower border extending 1 cm. below the edge of the ribs on the same side. The spleen was on the right side. The *x*-ray, after a test meal, showed the stomach on the right side. Electrocardiograms taken by Dr. Charles Leone showed the following results: Lead I, right arm to left arm—horizontal—was inverted. Lead II, right arm to left leg—long axis of the heart—was like Lead III in the normal heart. Lead III, left arm to left leg—vertical—was like Lead II in the normal heart. The right leg was then substituted for the left leg, with the following results: Lead IV, left arm to right arm—the electrodes reversed horizontal—was the same as Lead I in the normal heart. Lead V, left arm to right leg—long axis of the heart—was the same as Lead II in the normal heart. Lead VI, right arm to right leg—vertical—was the same as Lead III in the normal heart.

(To be concluded.)

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Special Meeting, Tuesday, November 3, 1918.

DR. THOMAS R. NEILSON, ACTING PRESIDENT, IN THE CHAIR.

The Surgical Treatment of Wounds of the Lung.—Major PIERRE DUVAL, of Paris, said that in the last two years the treatment of lung wounds in the French Army had changed from the medical to the surgical; that the surgical treatment consisted in excising the lung wound and treating it as one would a wound in any other part of the body. The chest was opened widely enough to take the lung out; it was then examined on all its surfaces; hemorrhage was checked, the lung replaced and the chest wall sutured completely. In the first half of the war in 300 cases of lung wounds treated medically there had been a mortality of from 25 to 28 per cent. By the surgical treatment in cases brought in with severe hemorrhage there were good results in from 65 to 68 per cent. of all cases. By the operative treatment of war wounds of the lungs the mortality had fallen from 28 to 9 per cent. The war experience in lung wounds Majjor Duval felt had opened a broad field for lung surgery in time of peace.

Gunshot Wounds of the Chest.—Colonel GEORGE E. GASK, of London, announced that a very great change had come over the whole of their treatment of gunshot wounds. At the beginning of the war, they had been horrified to find that every single wound was suppurating. Efforts to get clean wounds had been futile, and it seemed as if there had been a return to the pre-Listerian period. It was not realized that the essential treatment of all gunshot wounds was the early mechanical cleansing by open operation under aseptic precautions before the organism introduced by the missile had a chance to multiply and invade the tissues. A broad line of distinction was drawn between contamination and infection. In the majority of cases operation was done within 12 or 15 hours of the time of injury. For the first two years of the war the surgeons had feared to do any sort of operation on the chest. The men were put to bed, given morphine if in pain, a remedy for cough if there was cough, and it was hoped they would get well. Quite a large number did, but a larger number died, and a large number became extremely septic and had empyema with pus discharge. The only surgery that was done was the removal of an inch or two of rib and a tube put in. Throughout the time of the Somme fighting there had not been time to study the chest cases, for the number of urgent operable cases had been enormous. Gradually it was found possible to divide the thoracic cases into two categories: Those dying on the battlefield or within a few hours, and those dying in from 48 hours to two or three weeks. Of the former class death was the result of hemorrhage; of the latter, usually death resulted from sepsis. The next step had been to find the channel of infection, and the great principle arrived at was to effect an early mechanical cleansing of the wound of the chest wall and of the wound in the lung. The method had been to put the patient to bed, the chest being examined for complicating wounds, hemothorax, pneumothorax, movements of the diaphragm, position of the heart and for any indication of respiratory distress. *X*-ray examination was used whenever possible. Determining that the chest wall must be excised, the rib, or scapula, was cut down upon, it being found necessary often to excise ragged splinters with a pair of scissors. Very often bleeding was found in the costal artery, which they at first thought came from the lung. This was tied. Inserting a finger, there could be felt splinters of bone in the cavity or sticking into the lung. Such cases with the air sucking in and out were uniformly fatal. Later they had been led to enlarge the wound of entrance

that the hand might enter the thoracic cavity and remove foreign bodies. Rather to their astonishment the men stood these operations much better than anticipated. There had been banished forever the principle which the speaker had been taught to believe that handling of the wounded lung would cause renewed bleeding. Upon opening the chest the blood was removed and search made for foreign bodies, the lung was examined for foreign bodies as would be a coil of intestine. If the foreign body had penetrated into the lung, a fresh incision might be required. This could be made without fear except near the hilus; any bleeding was easily controlled by deep catgut sutures. The principle that a wound must be cleansed, it was said, must be applied in wounds of the lungs as in any of the soft parts. As evidence of the fact that the lung is able to take care of any organisms without abscess formation, gas gangrene of the lung was unknown in spite of the many cases in which foreign bodies were left in the lung. It was, therefore, a matter of practice to close every wound in the lung. The author was inclined to believe that restoration of function is accomplished much more quickly when the lung is at once put into as nearly normal condition as possible. Cleansing of the pleural cavity was regarded as of the utmost importance. The final step in the operation was closure of the chest, and this is done as in closure of the abdomen when possible—muscle to muscle, and skin to skin. An anesthetic might be given with safety if there was fair function on the side of the chest not opened. The opinion was expressed that the type of anesthetic, so long as it was skilfully given, was not of very great importance. In the after treatment the chest should be aspirated at regular intervals to determine that no infection was present. It was stated that probably not more than 30 per cent of penetrating wounds of the chest should be subjected to operation. In their experience the indications for early operation were: (1) Such wounds of the soft parts as would require operation in any other part of the body; (2) bleeding from that wound, intracostal hemorrhage; (3) fractured ribs; (4) cases with large foreign bodies lodged in the lung; (5) cases of pneumothorax in which air is admitted through the wound. In hemothorax without extensive wounds, splintered ribs or retained bodies, there was said to be at present a diversity of opinion. While the inclination was to operation, their practice was not to operate unless there was sign of sepsis. Theoretically there should be no such state as an infected hemothorax, but practically there were a considerable number of such cases. No means of telling which cases would become septic were available. It was believed that closure of the chest helped to expand the lung for every movement aids in this expansion as soon as the air is absorbed. If pus were formed a stitch might be easily removed and a tube inserted. The surgical treatment of wounds of the chest was now being practised in almost every hospital at the front line, and the surgeons had had the supreme pleasure of seeing many patients restored to health who would have died under the former treatment.

The Treatment of Chest Wounds by Artificial Pneumothorax.—Professor RAFFAELE BASTIANELLI of Italy said that in the Italian Army the treatment of chest wounds had followed almost the same steps as in the other armies. Early in the summer of 1916 there had been observed the necessity of an active intervention, and the conclusion had been reached that, except for a few puncture-like wounds, it was necessary to excise the soft parts and to remove the bone fragments, treating the chest wall in the same way as the teaching had been to treat wounds in any other part of the body, because it was felt that much of the pleural infection causing empyema, septicemia, and death was due to an infection coming from the outside. The chest wall was closed air-tight and without drainage, and generally this operation was performed under local anesthesia. It was through the untiring interest of one of the author's associates, Major Morelli, a pupil of Forlanini of Pavia, that the artificial pneumothorax had been introduced into the Italian Army, leaving the complete chest operation for the treatment of exceptional cases. Some lung wounds are such that air was not admitted to the pleural cavity from the outside, neither could it escape, so that the hemothorax and the pneumothorax were in a closed thorax; and when here there were no adhesions generally it was seen that the hemorrhage was either fatal; or it was profuse, or moderate; or did not show at the beginning, but appeared and was prolonged. This prolonged hemorrhage was due to the fact that inside the closed thorax there was the negative pressure of the lung which worked like a suction cup on the lung wound. Two very bad conditions, a movement of the wounded organ, and a suction on the wound itself, were thus presented. In many such cases of closed thorax wound Nature might effect a perfect or an imperfect cure. The mechanism of the cure by Nature was through the pressure exercised on the lung wound by the blood in the pleural cavity, by the air, or by both together. With 1500 or 2000 c.c. of blood inside the pleural cavity the lung might still expand. The lung, collapsed and immovable, presented a favorable condition for healing. It had been learned also that blood in the pleural cavity was dangerous not only as a medium for micro-organisms but also in favoring the formation of fibrous deposits which obliterated the sinuses of the pleura and produced adherences; also its presence did not favor expansion of the other side of the chest. Instead, if the pleural cavity were filled with air, the lung was compressed, hemorrhage, infection, and adhesions were prevented more easily, and even the big missile inside the lung sometimes remained without complication if immobility were maintained. With blood in the pleural cavity the lung was usually only partially retracted and bad functional consequences ensued. If the lung were surrounded completely by air adhesions did not occur, and when the lung began to expand the pleura would not contract adhesions so quickly that the expansion was prevented. Adhesions might occur later, but then the lung had already expanded and the function was good. For these reasons it was believed that there was advantage in removing the blood as completely as possible from the pleural cavity and in substituting air. Secondary hemorrhage was never seen. The current opinion that blood in the pleural cavity was efficient in checking hemorrhage was not true if in removing the blood air was substituted, inducing a positive pressure sufficient to cause collapse of the lung. It was believed that in every case in which a lung wound was demonstrated pneumothorax should be performed. This was done also in cases of contusions of the lung which were apt to be followed by complications. Contra-indications were evidenced when adhesions prevented the introduction of air or when the air escaped through a gap of the chest wall which could not be completely closed, or through the lung wound itself. Such contra-indications, however, were exceptional. The indications for complete operation in their practice were very limited, and when the chest is a closed one it was believed that it should be performed exceptionally. While if the chest were open, and especially if the opening were large, naturally it was more often indicated to inspect and treat the lung wound. There had been no case in which it was necessary to resort to a complete operation for hemorrhage. It was believed that the operation should be performed when a foreign body in the pleural cavity could be demonstrated. Closure of the open chest should be made as promptly as possible and there had been found useful the introduction in the chest wound of a small rubber bag which when inflated sealed completely the opening. These bags and the apparatus for performing the pneumothorax, devised by Major Morelli, were shown by lantern slides. In 206 cases of lung wounds with closed chest treated by pneumothorax alone or by thoracentesis and pneumothorax there had been seven deaths. Among the cured cases there were seen only 22 complications. Of the open chest there were 84 cases with a mortality of 19 cases, 22 per cent. Of these 19 eight had died in the first 14 hours. Of the 76 treated by pneumothorax after removal of the blood there was a mortality of 11 cases, 14½ per cent. There had been a great improvement in this series of open chest since the author's plan of suturing the chest wall air-tight was systematically adopted instead of plugging permanently the gap with the rubber bag. In 35 cases so treated there had been two deaths. The opinion was expressed that these results compared fa-

vorably with any result in any other army by any other means of treatment.

Surgery of the Lungs.—Colonel Sir THOMAS MYLES of Dublin said that it must never be forgotten that the man with a bullet in his lungs had a bullet in two places—in his lung, and also on his mind. It was to get rid of the bullet on his mind that the second operation was often undertaken. Sir Berkeley Moynihan believed that the mechanical effect of the bullet in the lung was in many cases comparatively small, while the effect upon the man's mind was very large. The only reliable method of examination was said to be by the *x*-ray, and for the removal of the foreign body Sir Berkeley Moynihan found that with few exceptions an incision at the level of the fourth rib offered an easy route of exit. The lung was to be handled as gently as possible in searching for the foreign body, and when located it was a simple matter to make an incision and extract it. A stitch was then inserted with a curved needle. It was of great importance not to encourage a too rapid inflation of the collapsed lung. It was of service also to maintain a pneumothorax for a few days when necessary to break down adhesions.

Later Stages of Gunshot Wounds of the Lungs.—Major G. GRAY TURNER of Newcastle-on-Tyne said that in the early stages of the present trouble it was not the custom to carry out any active surgical intervention; the practice of the surgeons at the front was reflected upon the practice of those in the stations behind the battle line. As a consequence quite a number of cases suffering from penetrating wounds of the chest and with retained foreign bodies came to the base hospitals. About the middle of 1915 it had been determined to see if the men could not be relieved by active surgical methods. It was found that many were suffering from incompletely absorbed hemothorax, some from neurasthenic symptoms, some from injury to the underlying lung. In a limited number of cases the foreign body in the lung gave rise to cough, hemoptysis, and symptoms suggestive of suppurative processes. Upon operation, band-like adhesions in the track of the bullet had been found, the site of persistent infection, due possibly to the movement of the lung. The best results in gunshot wounds were said to be obtained in those cases in which there had been a through and through wound. These men made a good recovery up to a certain point but broke down under the stress of military training. Upon opening some of these cases it was found that the blood was an organized clot. The lung was perfectly smooth as though encased in a sac. By splitting up the fibrous coating the lung was enabled to distend. A similar condition in the diaphragm was dealt with in the same way. The worst feature found upon opening the chest was that of adhesion of the base of the lung to the diaphragm. The speaker was inclined to think that a certain amount of the disability here found was due to the hemorrhage and want of expansion of the lung for a considerable time. The lung becomes retracted and this position was not overcome by the respiratory exercise. It was not fair to speak of these operations as though they were to be lightly undertaken. The risk, however, was very small. Recovery depended upon the amount of damage done to the lung tissue at the time when the operation was undertaken. Sufficient time had not elapsed to say what the ultimate history of these cases would be. It was not deemed enough to say that the patient could be returned to duty; the condition months or years hence must be known before one could speak with certainty. Chest surgery was regarded as a branch of war surgery not yet sufficiently practised but for which the time for development was ripe. The nearer to the battle front could be brought the first line of surgical defense the better would be the results. The success of thoracic surgery in this war, it was stated, had been a very good demonstration that the general principles of surgery were true wherever applied.

War Amenorrhea.—This affection must be compared to certain disorders in animals due to defective nourishment. If deprived of certain fodder, cows give less milk, and hens do not lay.—*Correspondenz-Blatt für Schweizer Aerzte.*

Miscellany.

State and Federal Cooperation in the Control of Venereal Disease.—Since the establishmnet of the Division of Venereal Diseases as a part of the Public Health Service plans have been worked out for State control and prevention of venereal diseases, and the United States Public Health Service has published a number of bulletins giving suggestions for the active prosecution of a campaign against these diseases to be carried on by State departments of health. Notification laws or regulations requiring the reporting of these diseases to health authorities have now been passed by nearly all the States, and the machinery for the control is rapidly being put into operation. The campaigns instituted follow the four principal channels, namely: (1) Educational: Acquainting the public with the nature of the diseases and the objects desired to be accomplished. (2) Law enforcement: Securing cooperation of the physicians in reporting cases, and of the police in apprehending prostitutes, vagrants, and such other persons as can be reasonably suspected of having venereal disease in communicable stages. (3) Propaganda to secure local funds for providing detention homes and hospital facilities for isolation and treatment of venereal diseases carriers who by their habits are a menace to the public health. (4) Establishment of increased facilities for early diagnosis and treatment. Attention is called to the fact that in putting any comprehensive plan into operation it is wise to do at once those things which may be done without special law or ordinance. Free diagnostic facilities and free treatment facilities may be established without additional legislation, though they do require money. As a war measure it is possible in practically all states to secure money for a venereal disease campaign as a part of a nation-wide patriotic effort to increase the efficiency of the fighting forces. There should be a Wassermann laboratory in each state and in large cities branch laboratories may be used. A chain of venereal dispensaries should be established so placed as to furnish treatment facilities for the entire state. Sufficient money must be secured to enable the State to assist in the maintenance of these dispensaries by furnishing free arsphenamine and about $1,000 for each clinic for clerical and other expenses. On this basis it is possible to establish these dispensaries, preferably in connection with existing institutions, in order to render less conspicuous the venereal clinic itself. These dispensaries should serve as centers for the distribution of arsphenamine. The minimum standards for clinics for venereal disease control recently adopted by Massachusetts are recommended for the consideration of other states entering on this work. It is also suggested that if State laws are insufficient proper legislation should be secured to prevent the treatment of persons suffering from venereal diseases by quacks and drug clerks. Since syphilis and gonorrhea have been declared diseases dangerous to public health and made reportable, a druggist has no more right to treat them than he has to treat smallpox, diphtheria, or scarlet fever. A final suggestion is that prisoners with venereal disease be treated and cured before discharge.

CONCERNING CERTAIN TYPES OF HEMORRHAGIC NEPHRITIS.*

By LEO BUERGER, M.D.,

NEW YORK.

ASSOCIATE ATTENDING SURGEON, MT. SINAI HOSPITAL, AND PROFESSOR OF UROLOGIC SURGERY, NEW YORK POLYCLINIC HOSPITAL AND MEDICAL SCHOOL.

THE recognition of the existence of various clinical forms of hemorrhagic nephritis, as well as the separation of the nephritides which are accompanied with frequent and profuse hematuria, into groups is of value particularly in facilitating the diagnosis and in determining the therapeutic indications of the urologist. Albarran was one of the first to call attention to the frequency of organic lesions in the kidney in many of those cases of hematuria, in which the diagnosis of essential hematuria or renal hemophilia had been made. The surgeon should be able to group those cases of doubtful hematuria in which we can find no gross organic lesion of the kidney—such as calculus, tuberculosis, or tumor—into cases of essential or idiopathic hematuria, cases of hemorrhagic nephritis of the Bright's type and the primarily hemorrhagic nephritides—those usually following infectious processes. Concerning the first two much has already been written. It is with the last of the three types of hematuria, that I wish to concern myself tonight, and I hope in discussing the hemorrhagic nephritis of infectious origin to be able to bring to the attention of the medical practitioner certain characteristic phenomena and objective manifestations that the urologist has learned to find, and which are concomitant manifestations of certain types of this disease.

It will not be my purpose to dwell at length on the etiology any further than to point out that rather striking is the frequent association of infectious diseases, or infections of the throat and tonsils, with the development of hemorrhagic nephritis.

In this particular the hemorrhagic nephritides, concerning which I shall speak tonight, differ from the hemorrhagic nephritis of Bright's disease.

Thus, Israel reports smallpox as one of the antecedent diseases, and possibly the cause of hemorrhagic nephritis in one case, and diphtheria and two attacks of rheumatism, as the causes in other cases. Leguéu operated upon a case in which a severe angina seemed to precede the development of hemorrhagic nephritis. Pousson believes that one of his cases was due to typhoid fever.

Pathology.—Concerning the pathology very little definite is known. It is supposed that just as in the case of the nephritides accompanied by pain, the so-called painful nephritides, the lesions are most frequently localized in one kidney. The lesions may involve the perirenal fatty envelope, the capsule of the kidney and the parenchyma.

The fatty envelope or fatty capsule is supposed to be the site of a chronic inflammatory process, but the extent of the lesion is not so marked and great as in the case of the painful nephritides. It is often absent, but may be pronounced as in the cases reported by Foisy, Israel, and Freeman.

As for the capsule of the kidney, alterations may be present in the form of milky plaques, or whitish bands that can cause deformation of the kidney. None of these changes are so marked as in the nephritides accompanied by severe pain.

As for the kidney, it is sometimes diminished in size, hard, and apparently deformed by the action of the capsule. In the majority of cases, however, it is rather larger than normal, and in some cases is said to be even elongated in the form of a sausage or rather spheroidal or globular in shape, depending upon the direction of its enlargement. In general, we may say that the renal tissue appears somewhat congested, has a violaceous tint, suggesting chronic hyperemia and congestion.

As for the histological lesions, these are not extensive, and seem to involve especially the glomerular system. In some cases, these changes are so minimal that it is necessary to make numerous sections to recognize any pathological changes at all.

Pousson recounts the case of Nicolich, where the left kidney had been removed for profuse hematuria. On examination by one of the most competent histologists in Vienna, this kidney was pronounced as practically free of any microscopic change. However, on further and more careful study, after numerous sections had been cut, Albarran was able to demonstrate distinct lesions of glomerular nephritis. Similarly, Israel was able to find minute microscopic lesions in a kidney removed by Sonnenburg, in a case considered a hematuria of hemophilic origin. Israel demonstrated the presence of numerous islands of interstitial inflammation and new-formed connective tissue.

According to the various authors, one may recognize in the case of hemorrhagic nephritis, lesions involving the stroma, interstitial lesions, parenchymatous lesions, and lesions involving

*Read before the Clinical Society of the People's Hospital, New York, April 10, 1918.

both parenchyma and stroma, so-called mixed lesions.

In short, if we inspect the findings of the most thorough investigators, we will have to believe with them that in practically all instances of hemorrhagic nephritis, some lesions in the parenchyma do exist.

Symptomatology.—In some cases no prodromal symptoms are noted, the hematuria occurring in a patient apparently in perfect health. In the experience of Pousson, the appearance of blood in the urine is more frequently preceded by lumbar pain, even though this be slight. At times there may be very severe pain, sufficiently marked to arouse the suspicion of renal colic.

Thus, firstly, we have the cases in which hematuria is the first symptom; secondly, the cases where the hematuria is preceded by attacks of pain or dull ache; and, thirdly, the hematuria in which there is a distinct history of angina, some febrile disease, some infection, influenza or typhoid, followed within a short period by evidences of hemorrhagic nephritis, or at least by hematuria.

The symptoms usually recur, so that the course is intermittent, occurring suddenly as some of the other diseases of the urinary tract do, where there are attacks of congestion. Some authors believe that these attacks are precipitated in some instances by fatigue, walking, or violent exercise.

In most of the cases, profuse hemorrhage has been noted, lasting several days, weeks, or even months, some patients having persistent bleeding over a period of years. When the hematuria lasts for such a long time, it is rare to find it continuous, there being intermittent, short, free intervals, during which no macroscopic blood appears in the urine.

It is a rule to find the hematurias become successively more severe in hemorrhagic nephritis, but there are exceptions to this general statement. In regard to the pain, we must divide this into two types: first, that which is due to the congestion of the kidney, and the hemorrhage into the kidney pelvis, with the increased tension of the capsule—therefore, a pain due to a sort of strangulation of the kidney; and secondly, the pain that is due to the passage of clots, the reno-ureterovesical pain, usually characterized by a certain amount of irradiation into the bladder, groin, or even into the extremities.

I think it would not be too audacious to assume that the mere passage of a considerable amount of blood without the presence of clots may produce sufficient irritation of the ureter to give the symptoms of pain, an example being afforded in the passage of fine uric acid and oxalate crystals.

Then, again, we must not forget that there are rarer instances of chronic nephritis, in which there is a long period, months or years, during which the patient complains of lumbar pain without hematuria. The *x*-ray examination may be negative, and the hematuria may not as yet have set in. This period may be called that of chronic nephritis with pain, or nephralgia without hemorrhage, and gives way to that symptom-complex which we regard as hemorrhagic nephritis; in short, nephralgia for a number of years followed by the development of chronic nephritis with pronounced hematuria. Some of these cases are incorrectly diagnosticated as chronic appendicitis.

In certain cases there is some tenderness of the affected kidney during the period of hematuria. In others, we can distinctly feel an enlarged organ.

Rather interesting is the circumstance that the blood in these cases is often intimately mixed with the urine, and may show no clots. Particularly, are the long worm-like clots, those so characteristic of bleeding from the kidney in cases of hypernephroma, absent.

As for the presence of other elements suggestive of the existence of nephritis, namely, albumin and casts, there seems to be no unanimity of opinion. Thus, in our own experience, *it is usually difficult to find any casts whatsoever* during the active stages of the bleeding, making the diagnosis still more difficult. Certain authors claim that the usual findings of a chronic nephritis obtain here too, namely, the reduced output of urea, reduced quantity of urine, the presence of casts, the diminished phenolsulphonephthalein output, and the increased nitrogenous products in the blood. In our experience we cannot corroborate or confirm these generalizations, at least during the early stages of the disease.

It is rather noteworthy that the general condition of these patients does not seem to suffer for some time. Those who bleed considerably may be pale and somewhat emaciated as time goes on, but for a considerable period of time their general state is good. Except for local complaints, ailments that accompany the original infection or are the sequelae of the original infection, the local pain and discomfort in the lumbar region and the hematuria, there are no symptoms. When secondary anemia is established, certain secondary symptoms appear that belong to this complicating condition, such as slight headaches, slight intestinal disturbances, shortness of breath, etc. These, therefore, are the consequences of loss of blood. Cases reported as having persistent headaches, disturbances of vision, dyspnoea, severe gastrointestinal symptoms, with possibly edema of the lower extremities, more properly belong to the classification of Bright's disease with complicating hemorrhage, than to the class which we here designate as hemorrhagic nephritis.

Illustrative Cases.—One of the most interesting of the cases that have come under our observation may be cited both because of the pathological inferences that could be made from a study of the cystoscopic lesions, and from the standpoint of the diagnostic deductions that could be drawn from a study of the clinical history.

Case I.—B. G., male, 21 years of age, was referred to me by Dr. L. Gross because of very active hematuria. Careful investigation of the history elicited the following: About one week previously he had been ill with a sore throat. For the past four or five days he had had fever, pain in the throat, and general malaise, the symptoms being regarded by him as indicative of a cold and sore throat. For the past three days he had blood in the urine. With the passage of blood he noticed an increase in frequency of urination, with the gradual onset of some pain during micturition, with discomfort during the act as well as some urgency. He

had never had any renal or bladder symptoms so far as he knew, and was fairly sure that he had never passed blood before. Renal colic or pain in the lumbar region was absent.

Examination of the urine showed numerous red blood cells, some hyaline casts, a large amount of albumin, and a few small clots of blood; in short, a very distinct history of angina, fever, malaise, followed by hematuria.

It was the cystoscopic examination done on June 5, and another one on June 10, that gave interesting and valuable information regarding the nature of the process that was responsible for the hemorrhages, or the escape of blood not only from the kidneys, but also from the bladder.

Cystoscopic notes, made on June 7, 1915.—The bladder is found to contain numerous small blood clots. The posterior wall of the bladder near the base is hemorrhagic, seems to be swollen, reddened, but the ureters do not appear to show any lesions whatsoever. In the region of the trigone there is a mass with an irregular villous surface, that undoubtedly represents partly decolorized blood clots. In the right paratrigonal region there are numerous hemorrhages, and also a small blood clot. Catheterization of the ureters (after the injection of indigo-carmine for the purpose of estimating the functional activity of the kidneys) is easily performed, there being no obstruction in the ureters. There is some delay in the output of the indigo-carmine, none being excreted in the specimens obtained from the right side during a period of at least 17 minutes after the injection, whereas, the left kidney function seemed to be a little more active, in that the specimens were slightly green after a period of 11 minutes.

The examination of the urinary specimens showed the following:

Right Kidney—Reaction, neutral; albumin, trace; urea, 0.1 per cent.; microscopical, few epith. cells, few red blood cells, few pus cells, hyaline and finely granular casts; culture, sterile; tubercle bacilli, negative.

Left Kidney—Reaction, acid; albumin, trace; urea, 1.4 per cent.; microscopical, many epith. cells, many red blood cells, few pus cells, hyaline and finely granular casts; culture, sterile; tubercle baccili, negative.

Bladder—Reaction, acid; albumin, much present; urea, 1.6 per cent.; microscopical, blood; culture, staphylococci and colon bacilli; tubercle bacilli, negative.

In brief, the specimens obtained from the two kidneys showed that the right kidney was evidently somewhat inhibited in its action, as evidenced by the very low output of urea, and poor excretion of indigo-carmine. Furthermore, both kidneys were evidently bleeding in very small amounts, the urine of both kidneys containing hyaline and granular casts. Suggestive of the existence of an inflammatory process, or of an acute exudate, a nephritis, or possibly indicating a complicating pyelitis, was the presence of a few pus cells in both specimens. But the amount of pus was not sufficient to warrant a positive diagnosis either of a suppurative nephritis or of a pyelitis.

It seemed very evident, therefore, that we were dealing here with two lesions, one suggestive of a nephritic process in both kidneys, attended with hemorrhage, and another lesion, a vesical lesion, characterized by numerous submucous hemorrhages and suggillations.

On June 10, 1915, a second cystoscopic examination was made to further study the nature of the lesions in the bladder, and to determine whether these were merely a part of a general process, of which the involvement of the kidneys was but one expression or manifestation, or as to whether some other local condition was present or not.

The cystoscope again revealed extensive hemorrhagic areas occupying the region of the trigone, of the paratrigonal region, and of the posterior wall of the bladder. Some of these submucous hemorrhages were present in the form of gyrate areas, others were small and punctate, but evidently of considerable depth by reason of the protrusion that they caused in the mucous membrane. Catheterization of the ureters delivered urine which contained such small traces of blood in the specimens from both kidneys that a diagnosis of renal hemorrhage was impossible at this time. Examination of the urinary specimen showed an absence of tubercle bacilli on June 16, the bladder urine, however, exhibiting a moderate amount of albumin, occasional granular casts, numerous red blood cells, and a very few white blood cells.

The coagulation time, taken on June 11, was 13 minutes; red blood cells, 4,500,000; white blood cells, 13,200, with 73 per cent. polymorphonuclear cells, and 27 per cent. lymphocytes.

To sum up the findings at the second cystoscopy: *evidences of extensive bladder hemorrhage, no active renal hemorrhage, but findings suggestive of nephritis.*

The patient remained under my observation until June 15, when he was so much improved that he was discharged from the hospital. On January 6, 1917, about one and a half years later, he consulted me again, saying that he had apparently been perfectly well until December 13, 1916. He thinks he caught cold, had fever, headache, general malaise, pain in the back, legs, and in the joints. Within a very short period, possibly less than a day, his urine again became bloody. Because of the fever and general symptoms he remained in bed for three weeks, the symptoms gradually subsiding, the urine becoming almost clear. However, a few days ago the urine again became bloody, so that he was sufficiently anxious about it to consult a specialist. Succinctly, then, after an interval of about a year and a half, there was a return of general symptoms, "a cold and hematuria."

January 9, 1917, I examined his bladder again with the cystoscope, with the following result: The bladder interior was practically negative in contrast to the findings one and a half years ago. The specimens from both kidneys contained blood, without any pus cells; the cultures from both kidneys and the bladder remained sterile, tubercle bacilli being absent. The output of indigo carmine was about equal on both sides, appearing in good concentration within about 14 minutes after the injection. The detailed urinary report is as follows:

	RIGHT	LEFT	BLADDER
Reaction	Acid	Acid	Acid
Albumin	Faint trace	Good trace	Heavy trace
Sugar	.....	.....	Negative
Urea	1.8	1.6	1.5
Microscopical	Few epith. cells Some red blood cells No pus cells No casts	Few epith. cells Some red blood cells No pus cells No casts	Few epith. cells Many red blood cells No pus cells Few finely granular casts
Culture	Sterile	Sterile	Sterile
Tubercle bacilli	Negative	Negative	Negative

From this cystoscopy we could conclude that the hematuria was still present, but evidently subsiding, that hemorrhagic lesions in the bladder were absent on this occasion, that the examination of the specimens suggested strongly the diagnosis of nephritis, and in conjunction with the history, made the assumption warrantable, that an infectious process may have again been responsible for the recurrence of bleeding in the kidneys.

Phenolsulphonephthalein test, January 21, 1917, showed an output during the first hour of 35 per cent.; second hour, 21 per cent.; *total*, 56 *per cent. in two hours.*

The patient was kept under observation for some three or four weeks, during which time the hematuria gradually subsided, although not completely, so that a few red blood cells were always present in the urine, even after his discharge, early in February, 1917.

In further elucidation of the clinical picture of this type of hemorrhagic nephritis and of further corroborating the value of cystoscopy as an aid to diagnosis, I may be permitted to cite the case of a boy about six years of age who was referred to me by Dr. S. Sobel because of hematuria.

CASE II.—B. L., boy of 6 years, had tonsillitis two weeks previously. Since then hematuria appeared, the exact day of the onset not having been noted. For the last four days there had been some abdominal cramps, a diffuse ache in the bladder region, and the urine was macroscopically bloody.

Examination of the urine showed considerable albumin, the sediment being composed mostly of red blood cells, numerous in number, possibly a few pus cells, with possibly more white cells than could be accounted for by the presence of the blood. *X*-ray examination was negative.

Cystoscopic examination on May 13, 1916, under gas anesthesia, showed numerous hemorrhages in the posterior wall of the bladder. Blood was seen coming from the left kidney. The question of the presence of blood in the right kidney urine could not be determined, because the efflux was barely colored, and catheterization of the ureter was not done. The efflux from the left ureter, however, indicated left renal hematuria.

Within two weeks after the cystoscopy the patient's symptoms had subsided, and according to the family doctor's statement the patient has been well ever since.

Curiously enough, another member of the family was attacked similarly about the same time after an attack of tonsillitis.

In short, *hematuria, evidently of renal origin, associated with bladder hemorrhages, affecting a case in which there was a distinct history of an infection of the throat, which was followed by an involvement of the urinary tract.*

Clinical and Pathological Deductions.—It was my purpose in discussing somewhat in detail these two interesting cases exemplifying a group which not infrequently comes under the observation of the urologist, to present for your consideration the possibility of the acceptance of a new viewpoint regarding the pathogenesis of the hematuria in these cases, and to call attention, furthermore, to the great value of a thorough examination, by means of the cystoscope and the *x*-ray.

Little is known regarding the causation of renal bleeding. In the cases of bilateral nephritis, which the French authors regard as belonging to the Bright's type, or the so-called chronic nephritides, we may invoke as an explanation of the hematuria, either a diminution of protein substances in the blood, or a change in the blood by reason of toxins, possibly retained toxins. However, clinical facts tend to show that unilateral cases—and the cases cited more frequently belong to this type—are more apt to be attended with hematuria, a circumstance which could hardly be in keeping with the toxic theories or with the theory of alteration of the constitution of the blood. It was argumentation along these lines that led Pousson to believe that renal bleeding may be due to limited local changes in one or the other or both kidneys, and that anatomical changes, particularly in the glomeruli may be responsible.

On the other hand, there are the views of those who believe that the renal hemorrhage is due to reflex vascular disturbances, initiated by irritation of some renal nerve (Rovesing).

And then again we have the views of Lancereaux, whose conception was that an angioneurotic process obtained in these cases.

The question then arises: *Is there an antecedent local disease of one or both kidneys which is responsible for the renal bleeding? Or may not the renal bleeding be the primary or antecedent phenomenon, evoked by an infection,* and *may not this bleeding be the precursor of renal changes, which we interpret later in specimens that are removed, as chronic nephritis, glomerular nephritis, or interstitial nephritis?*

If we study carefully the association of bladder hemorrhages in these cases, we cannot refrain from suggesting some sort of hypothesis as the following.

By virtue of some toxin, bacterial agent, or virus, hemorrhagic lesions occur. These lesions in the cases of hemorrhagic nephritis above cited are particularly known to occur in the urinary tract where the clinical and cystoscopic evidences demonstrate them to have appeared or to have given rise to hemorrhage, not only from one or both kidneys, but also in isolated and disseminated patchy areas in the bladder interior. For what other explanation could account for the appearance of the suggilations in the bladder interior? Does not the presence of the bladder hemorrhages at least suggest that the *same cause is responsible for similar lesions in the kidney;* and that, as a result of these hemorrhages in the kidney, the urine is either directly admixed with blood in the kidney tubules by reason of the parenchymatous hemorrhages, or becomes secondarily bloody by virtue of the secondary changes that have been brought about in the renal tissue? That such an assumption or hypothesis is not fanciful will be clear when we consider the many other hemorrhagic diseases in which multiple hemorrhages occur, not only in the integument, but also in the intestinal tract. In accord with this line of reasoning, we may assume that certain secondary interstitial and glomerular changes in the kidney are rather the product of the initial hemorrhagic renal disease than the cause of the original or primary hematuria. After such interstitial and glomerular changes have become established, recurrences of the hematuria may be due either to the chronic renal disease thus engendered or to recurrences of the same type infection which had brought about the first attack.

In brief, we may be permitted to entertain the thought that another modus in the elaboration of the renal pathological lesions may be at work than the usual primary or initial nephritis.

Be that as it may, it seems to me that a very important observation, one which throws some light upon the classification of these cases, and one most useful clinically as well as from the therapeutic standpoint, is the recognition of the association of bladder hemorrhages with renal hematuria, a finding that can be discovered only with the cystoscope. For it may be mentioned here in the way of anticipation, that it is this type of case *par excellence*, as well as that type of so-called essential hematuria—many of which really belong to this group—that sometimes responds in a most remarkable manner to the simple operation of renal decapsulation.

The analysis of another set of interesting cases that have come under my observation, is suggestive of the possible relation between so-called influenza or grippe infection, and the development of bladder hemorrhages with and without signs of renal hemorrhage at the time of cystoscopy.

Case III.—In one case that came under my observation on the 9th of January, 1917, a woman of about 36 years of age (L. I.), there was a history of a sore throat about two weeks previously, with what the patient regarded as grippe. Ten days later hematuria commenced, without pain in the bladder, but with some urgency and urinary frequency.

Cystoscopy on January 9, 1917, disclosed extensive intravesical hemorrhages, one rather large hemorrhage behind the left ureter, with rather extensive ecchymoses or suggilations in this neighborhood. There was a similar smaller hemorrhage behind the right ureter, but the usual signs of cystitis were absent.

The catheterized specimens from the ureters showed blood coming down from both kidneys in small amounts, the left-sided specimens being macroscopically bloody. *X*-ray examination was negative. Cultures showed *Bacillus coli communis* in all the specimens, which, however, is not an unusual finding in females, and the significance of which is not at all clear in this case.

A careful study of this case convinced me that we were not dealing with a pure or simple cystitis, the vesical picture of a cystitis, but rather that of a purpuric condition, limited to the bladder mucous membrane.

Inasmuch as there was no recurrence in this case since the time she first consulted me, no further data have been obtainable. It is not unlikely, however, that this case also belongs to the type above alluded to, although the possibility of a colon bacillus infection can not be absolutely ruled out. Certain it is, however, and definitely proven was it by the observations made here, that multiple hemorrhages in the bladder mucous membrane may be the product of toxins, as in the other cases of grippe and sore throat.

That cases of this nature, where the bleeding becomes intractable and alarming, sometimes respond in the most miraculous manner to decapsulation, the following instance from my case records will illustrate:

Case IV.—A. K., male, 27 years of age, consulted me on June 21, 1915, referred by Dr. S. M. Roth for "kidney trouble." During the month of April about two and a half months previously, he had had a severe attack of grippe, which lasted for some time, and which made him ill for almost a month. Either during or following this attack of grippe he had had some dull ache in the left lumbar region, and for some two weeks or more had a great deal of blood in the urine.

Cystoscopic examination on June 21, 1915, showed a negative bladder, specimens from the left kidney showing large amounts of blood. The right kidney was excreting normally, showed good function, whereas the function of the left kidney was markedly diminished. *X*-ray examination was negative.

Because of the profuseness of the hemorrhage, which appeared to be alarming, and because of the patient's anxiety and that of the family physician, it was deemed advisable to explore the left kidney, although the *x*-ray examinations were negative.

The phenolsulphonepththalein test was 28 per cent. in the first hour, 16 per cent. in the second, a total of 44 per cent. in two hours. The urea-nitrogen was 14 mg.; uncoagulated nitrogen, 32 mg. per 100 c.c. of blood.

On June 31 I performed an exploratory operation on the left kidney, did a nephrotomy, and decapsulated the kidney. The left kidney was found somewhat enlarged, there being fairly marked evidences of the presence of a perinephritis, particularly at the upper pole. The kidney was delivered. No stones were found in the pelvis on palpation, and a small incision was made through the parenchyma through which the exploring finger was able to palpate the interior of the kidney and pelvis. No calculus could be discovered. Decapsulation was then performed, the kidney replaced, and the wound closed in the usual manner.

Four days after the operation there was a very noticeable diminution in the amount of blood in the urine. Nine days after the operation there was almost no blood present, and on July 7, two weeks after the operation, the urine was practically clear. Since then no bleeding has recurred. The patient was discharged on July 7, cured.

On September 8 of the same year, in a communication received in answer to my inquiry, the patient notified me that as far as he knew he was perfectly well. In short, a very strikingly interesting example of the value of decapsulation in some of these interesting cases.

If I have burdened you with a rather extensive account of some of the patients that have come under my observation, my purpose has been to call to your attention the value of early application of the cystoscope in cases of hematuria. I have not gone into the details of differential diagnosis between hematurias of this type and the hematurias due to other causes such as tuberculosis, calculus, tumor, angioma, hydronephrosis and other lesions of the kidney, but my aim has been to emphasize the value of the urologic methods of examination, in the recognition of certain types of nephritis that do respond to operative intervention, and also to place before you for consideration, a new viewpoint in the pathogenesis of hemorrhagic nephritis, a viewpoint which may be of more than mere passing interest.

1000 Park Avenue.

EXPERIMENTS WITH A NEW AND MOST EFFICIENT REMEDY FOR PULMONARY AND LARYNGEAL TUBERCULOSIS.*

By F. TWEDDELL, M.D.,

GREAT NECK, LONG ISLAND, N. Y.

On July 4, 1914, I published in the Medical Record an article entitled "Cause and Prevention of Pyorrhea Alveolaris and Furunculosis," and in it I advised the use of sulphur and dilute sulphuric acid for these infections, as I found these drugs very efficacious in my practice, especially for boils. In this article I also mentioned that "J. and R. J. Reynolds of London reported wonderful results during a number of years from the use of dilute sulphuric acid in a variety of pus conditions, *i.e.* boils, carbuncles, and streptococcic infections. Cases even of bronchiectasis and pulmonary tuberculosis (*sic*) were markedly benefited."

Shortly afterward I received a letter from Prof. Charles Baskerville of the College of the City of New York. He stated that he was very much interested in my paper and would like me to send him two reprints, one for himself and one for a friend of his, a chemist in Chicago, Dr. Edward Gudeman.

In January, 1915, I received a leaflet from Dr. Gudeman, advising physicians to try inhalations of sulphur dioxide in the treatment of pulmonary tuberculosis, and as he had had no experience he left the method of treatment in the hands of physicians. He mentioned that sulphur dioxide could be inhaled by burning sulphur, sulphur candles, or by liberating the gas contained in liquid form in a steel tank.

In subsequent letters in reply to my inquiries he stated that "the value of sulphur dioxide is twofold; by chemical action it destroys the germs, and by mechanical action it dissolves the diseased tissue, loosens the mucous matter, and thereby exposes new and more healthy tissue to do the work required. It is the can-opener of the lungs."

*Read before the Society of the Alumni of Bellevue Hospital at the Yale Club, New York, Oct. 2, 1918.

He concluded his last letter saying: "I feel confident that inhalation of sulphurous acid will be beneficial in the treatment of tuberculosis, absolutely certain of it, if tried on patients in the first stages." This last sentence contains an astounding statement.

Months went by and I often pondered over the matter contained in these letters. Could it be true? Would a great chemist make such radical statements without indubitable grounds for them?

In December, 1915, I had my first opportunity in the person of a young Jewish woman. On examination the signs in her lungs pointed to a far advanced stage of phthisis. Her former physician agreed with me in considering her case a hopeless one. She took the treatment faithfully, and a month later I met her walking up a hill. I was very much surprised, as she had not been able to do this before. She told me that she was feeling ever so much better and was thinking of returning to New York. I advised her to wait another month, which she did, and improved steadily. On returning to the city her relatives and neighbors objected to the treatment, and after a couple of weeks she gave it up. About two months later I got news from her husband that she had a violent hemorrhage and passed away after two days' illness.

This was an unusual case. Before treatment this patient was so sick that she had given up all idea of returning to the city. After two months' treatment she felt better in every way, and her neighbors noticed the improvement.

The next patient was a married woman, thirty-nine years old, who came to my office on March 10, 1916, complaining of a chronic cough since the middle of December, 1915. She stated that the medicine ordered for her by another physician had not stopped the cough. Examination revealed the cardinal symptoms of incipient phthisis, viz., persistent cough, night sweats, loss of appetite, strength, and weight, dyspnea on exertion, pulse 96, temperature by rectum 99 6°, blood pressure, systolic 126, diastolic 92. I heard a few rales at the lower angle of the left scapula. The sputum was negative. Three weeks after treatment she had gained 2¼ pounds, felt perfectly well, and had no subjective symptoms. Three months later she had gained 15 pounds and her next-door neighbors, whom I knew well, told me she was apparently perfectly well. In the meantime I had met the physician who had previously attended her and discussed the symptoms with him and he had no hesitation in saying that this was a case of incipient phthisis. I thought the result of the treatment truly remarkable and henceforth I was very anxious to try it on other cases.

The next patient, a married woman, twenty-six years old, a native of the West Indies, of Spanish descent, came under my care when she was about eight and a half months pregnant with her first baby. She had been suffering from a chronic cough for over a year and was a Christian Scientist. On examination she gave the typical symptoms of phthisis and showed the following signs: consolidation at the right apex down to and including the second interspace in front and down to the spine of the scapula behind.

Two weeks after the birth of her baby, I put her on the new treatment. Although I watched her carefully, I purposely did not examine her chest for three weeks. I felt sure that something extraordinary would happen to that consolidation. Meanwhile she nursed her baby, taking the precaution on each occasion to cover her nose and mouth. She kept no servant and consequently did all the housework, including cooking and washing. Her subjective symptoms improved steadily in spite of adverse circumstances. Born and brought up in a hot climate, she could not stand the cold, and therefore lived in overheated and ill-ventilated rooms, seldom taking walking exercise or even fresh air.

When I examined her lungs at the end of the three weeks to my surprise the consolidation had completely disappeared, and there were only a few rales at the apex in front and behind. This was an amazing experience. The consolidation had behaved as it does in a pneumonia. If the treatment could do this marvelous feat, what would be its limits?

This patient was a frail little woman, who never weighed more than 100 pounds and now was only eighty-six. Nursing sapped her strength and was discontinued after three months, although she had milk enough for two babies. Her infant was a magnificent specimen and weighed then about fifteen pounds. On the advent of cold weather she yearned for the tropics, and heated her little bungalow more and more. In November, 1916, she left for the South, weighing ninety-two pounds, but she still had a few rales at the right apex. I advised her to take the apparatus with her, but she refused to do so. I heard later that she went back to Christian Science and died eighteen months after she left me.

On September 16, 1916, a patient came to my office complaining chiefly of dyspnea on exertion and cough since May, 1916. He had the cardinal symptoms of phthisis and the examination revealed crepitant rales at both apices and dullness over left apex with increased voice and whisper. The sputum was positive. He had just spent several weeks in Sullivan County, but without any benefit. A week after commencing treatment he was able to resume work in his business, but was given light jobs to do. Three weeks later the night sweats stopped and he made steady improvement. He coughed for a few minutes every morning on getting out of bed, and I attributed this to pleuritic adhesions. I examined his lungs at intervals and found no rales. I saw him about three months ago, and he was apparently well and at work.

On May 1, 1917, I went to a certain hospital. The physician in charge, after having heard my story, flatly refused to allow me to use such a poisonous gas on his patients. When asked whether he had ever tried it, he replied that he never had and never wanted to, but in the end I had my way. The interne selected four patients, only one of whom was interesting from my point of view. He was unmistakably tuberculous, with crepitant rales at both apices, a pleurisy on the left side, and broncho-cavernous voice and breathing near the right nipple, the size of a half-dollar. The sputum was positive. I asked the interne what he thought of this, and he replied that it was a small cavity. I told him I believed it to be a consolidation because of its size and added that we should know in a few days, as a consolidation would disappear whereas a cavity would of course stay. I had treated only one consolidation before, but just the same I was sure it would act in the same manner. The interne, of course, did not believe a word I said. Two days after starting treatment I told the interne that I would like to make a more careful examination and keep notes of it. When I examined the patient I put the stethoscope over the area in dispute and heard only vesicular breathing. I then asked the interne to locate the cavity. He searched for quite a while and his embarrassment and fruitless search for it amused me greatly. Three days later the same patient told me that an instructor appeared with a party of students and after looking at the chart he examined him, and then threw down the chart angrily, saying, "rotten examination." Now what was I to do? I could not have discussed this matter with the attending physician, as he would have told me that the interne had made a mistake and that there never was a cavity nor a consolidation. A few days later I decided to leave this hospital, as no one was interested in my experiments.

Early in January, 1918, I decided to try another hospital. I selected four patients. The first, a young girl of 13 years, had cavities at both apices, and I was about to reject her, when I noticed that she had aphonia. She told me that she began to lose her voice in September, 1917. She had been in this hospital since December 13 and no one had heard her speak aloud. She had no dysphagia and was therefore a most favorable case for treatment. Examination of her larynx showed edema of the arytenoids and vocal cords, these structures were pale, and shiny. I did not notice the epiglottis. On January 7, *x*-ray pictures were taken and I started treatment the next day. On January 15, the other three patients greeted me with joyful exclamations and informed me that "Edith is beginning to talk already." I noticed that Edith phonated every 5th or 6th word, and a week later she was able to speak aloud but was hoarse, like a person recovering from a cold. Three weeks after treatment she spoke well, and was only slightly hoarse.

I now asked the visiting physician to examine the patients and he flatly refused to do so, remarking that it would be unnecessary as there could be no improvement in so short a time. I then referred to Edith, and was told she was a "wonderful spontaneous recovery." I had never heard of a spontaneous recovery within three weeks, and several prominent laryngologists of New York agreed with me.

The other three cases were interesting and instructive. The visiting physician selected two of them, marking on the chart of one, "right apex late second stage," and on the other, "bilateral second stage." He did not approve of the third case, and I cannot now recall why I selected her unless because of her advanced condition.

On January 10, I saw the *x*-ray pictures and the report. There were no consolidations, only cavities, fibrous filtrations, etc. What was I to do now? I had come to the hospital to demonstrate the disappearance of consolidations under my treatment. If I selected another lot of patients I would have to give up the laryngitis case, and might not get another like her. I was afraid to mention that I would treat her, as the visiting physician would probably consider my request absurd. I therefore resorted to camouflage and said: "Since there are no consolidations, I will try it on the fibrous infiltrations." I was not wrong in this.

Immediately after I saw some of my medical friends and told them about this episode. I was warned that I had staked everything on a case of laryngitis, which I had never treated before.

I noticed improvement in the lungs of all the patients. Rales disappeared very rapidly from below upward, that is to say up to the third rib in front and up to the spine of the scapula behind. Above these lines, rales took much longer to disappear. I noticed that they staid longest at the inner border of the first interspace near the sternum. Behind they were last to go in the alarm zone.

One patient, M. O., had very loud sibilant sounds and not only she herself noticed this wheezing, but the other women heard it too. Only a week later they all informed me that they heard no more wheezing, and on examination I found very few sibilant sounds.

The *x*-ray report was incorrect, for in the case of the woman, Mrs. J., designated on the chart as "bilateral second stage," a cavity at the right apex only was mentioned, yet there was bronchial voice and breathing above the spine of the left scapula, but no such signs in front, only rales. I watched this consolidation and noted that it disappeared on January 29, in three weeks exactly. It first cleared up near the shoulder and staid longest in the alarm zone. I learned something more; there were two women with temperatures previously always over 101 deg. and during the fourth and fifth weeks at the hospital the temperatures were at or just below 100 deg.

The reason why on physical examination cavities are sometimes mistaken for consolidations, as was the case above, is very simple. You must have a consolidation before you can get a cavity. The latter starts in the center. This will at first give you all the signs of a consolidation. Now when you begin treatment, the chemical action of sulphur dioxide kills the germs and the diseased tissues are detached from the living tissues. The same action takes place with antitoxin in diphtheria. Two of my patients told me that after a few days' treatment they experienced an occasional pain at the apex and then felt as if something had got loose there, and that a little later a lump was felt in the lower part of the chest, pointing exactly to the bifurcation of the trachea. They then coughed and brought up a thick lump of mucus.

These patients made these statements of their own accord without leading questions. I will read you an extract from a lady's letter whose husband I am treating for phthisis. She writes: "On Tuesday the cough was more frequent and he complained of a fullness as he expressed it, in the chest on the left side. This has passed away, and yesterday Saturday, for a brief period he had a peculiar feeling accompanied by pain, in about the same place. The pain finally ceased, after which he said it seemed as if something which had been clogged had cleared away." Here we get the mechanical action of Gudeman's can-opener.

On February 13, my last day at the hospital, when I examined Edith's lungs I noticed cavernous voice and breathing in a small area to the outer side of the right nipple, which had not been there before. This shows that x-ray findings in regard to fibrosis are not always correct.

In July, 1918, I decided to try still another hospital. I exacted a promise from the visiting physician to examine the cases with me at least once a week. We selected two women with consolidations at both apices. I remarked to him that it was not always possible to be sure of consolidations, for if large they would, after treatment give the signs of unmistakable cavities. I also selected two men, one had aphonia and had had his epiglottis removed a few weeks before and now complained of soreness in the throat "like raw beef." His lungs were also involved. The other man complained of severe dysphagia

and his throat was tender to the touch. He could take only warm semi-liquid food. He could not eat crackers or bread, nor could he swallow any cold liquids. He also had marked dyspnea, with difficulty going up one flight of stairs. His lungs were also involved. The assistant laryngologist reported marked ulceration and infiltration of the larynx.

A week later, on July 22, we examined the patients. The left apices of both women showed only normal vesicular breathing and no rales. The right apices showed cavernous breathing and rales. The visiting physician made no comments. We then went down to another floor and examined the men. The first man felt more comfortable. The other man could eat everything now, hot or cold, soft or hard. The throat was no longer tender to the touch, and he had that morning early, spoken a few words aloud for a few minutes. He also told us that when the elevator was not available he walked up four flights of steps without losing his breath.

I asked for more patients and was referred to the intern. For nearly six weeks I begged the intern for consolidation and laryngeal cases, but he never had any time, or could not find any, although there were over 300 patients in the hospital. I then decided to leave.

On July 4, 1918, a patient, forty-nine years old, came to my office complaining of a slight cough for the past two months and dyspnea. His previous history was as follows: About 1901 he was operated on for mastoiditis of the left ear by a New York specialist, and four or five similar operations were performed during the next three or four years. At the last one the much enlarged cervical glands on the left side were excised. There is a profuse and constant evil-smelling discharge, which has existed for the past twelve years, and no treatment has been able to stop it. He has no night sweats, weight 136 pounds, height 5 ft. 11 in, temperature by mouth 99°, pulse 92 and regular, blood pressure, systolic 122, diastolic 92. Examination: very slim, deep depressions above clavicles, enlarged veins on upper part of chest in front. Whisper and voice louder on left side in alarm zone, with occasional crepitant rales. Few rales below and to outer side of right nipple. Examination of sputum: abundant pus cells very much degenerated, no tubercle bacilli; discharge from ear: few very much degenerated pus cells, no organisms present. Examination of ear: no drum membrane, an opening in posterior part of canal communicating with the mastoid, mucopurulent foul discharge.

In spite of the laboratory reports I considered this a case of chronic tuberculosis of the lungs and middle ear, and told the patient that I hoped I was correct, for in that case I could help him greatly. On July 9 he began treatment. On July 20 the discharge stopped. For the next three weeks he felt itching in the ear. During the week ending August 30 numerous dry scabs dropped out of the ear. He has had no symptoms since and his lungs are now clear. The specialist who operated on him and treated him for several years replied to my inquiries as follows: "This case was a very severe one. I have no doubt he was tuberculous at the time and his healing was very much retarded on account of his physical condition."

It had occurred to me that the inhalations of sulphur dioxide might be beneficial for other conditions as well as phthisis, especially pertussis. Consequently, when I was called in on August 31, 1916, to treat a lady and her daughter, aged nine years, for pertussis, I suggested my new treatment. They consented very readily, as they had tried everything else without relief. The mother had been suffering for a month and her daughter for two months from this affliction. That afternoon both patients began treatment.

I paid a visit 24 hours later—they were feeling very comfortable. The cough was slight and did not bother them at all, and they passed the first restful night for weeks. Forty-eight hours after starting treatment both patients stated that they had not coughed that day. I watched them for several weeks but no symptoms of pertussis returned. This seemed promising, but the results were not as good as I had expected. For out of a total of 26 patients only 10 were cured within three days, and of the latter, the oldest was about 36 years and the youngest 15 months. The treatment had no effect whatever on the other 16 cases. It is a curious fact that all the 10 cured cases were in Summit, N. J., where I lived until June 1, 1918.

The medical literature gave me no clue for further investigation, but the parents of some of the patients informed me, that many years ago, children suffering from pertussis, were taken near the gas plants and *some* of them recovered very quickly. I also heard from other sources that children were taken for runs in the Scranton coal mines, and that *some* of them recovered rapidly. I shall refer to this matter later.

We are then forced to the conclusion that there is more than one type of germ causing pertussis. One is killed by sulphur dioxide and the other remains immune to this gas. This confirms the statements of several physicians, that pertussis is not caused by a single germ; see for instance Holt's "Diseases of Infancy and Childhood," 1917 edition, page 1004.

In March, 1918, I wrote to Dr. Gudeman, relating some of my successes with his treatment, and received a reply dated March 22, 1918, from which I give some extracts:

"From your own experience with the medical profession, you can easily figure out how much more chance I have, a layman, to get the medical profession to actually try out the use of sulphurous acid inhalations. I had all plans perfected to have the treatment tried at the Municipal Tuberculosis Sanitarium here, but through political disturbances, the matter was dropped. I tried to have the Rockefeller Institute take it up, also the U. S. Medical Department. They were too busy and could not consider new work. You will note that chlorine inhalation is now used in the treatment of meningitis carriers, ... it has also great curative value in tuberculosis and other respiratory diseases. It would be a very long story to give you the outline even of what led me to recommend the use of sulphurous acid gas. It is based on personal observation and then study of prevalence of the disease.

"Immunity to respiratory diseases seems to exist in those occupations where gases having antiseptic effects are produced. Have you noticed that tuberculosis is not a disease found among the workers in the electric industries around Niagara Falls, none, so I have been told, in any of the generating rooms nor in the chlorine plants? To what extent is that due to the chlorine, or sulphurous acid, or nitric acid and nitrous fumes in the atmosphere?

"While sulphur is very inactive and if administered as such, is passed off into the feces as sulphur, a relatively large amount goes into combination. This is not surprising for sulphur is dissolved in alkaline juices and then is active and forms sulphur compounds."

If we examine the medical literature on the subject of phthisis, we soon discover that certain occupations are comparatively free from this curse and others are immune to it. I have here Fishberg's "Pulmonary Tuberculosis" and on page 98, you will notice that "coal dust prevents the development of phthisis, and that miners are less subject to phthisis than all other occupied males." Again on page 99, Fisac reports that in Spain the workers in quicklime and plaster of Paris are immune to tuberculosis, despite the fact that they live in squalid dwellings and are underfed.

To discover if this immunity exists among lime and plaster of Paris workers in this country, I obtained through a New York chemist, the address of the manager of the largest manufacturer of plaster of Paris in Canada. I wrote to the manager and asked him for statistics and in his reply he stated that not a single case of phthisis had been known among the men during the past 25 or 30 years.

Another manufactory in Canada reported equally favorably.

I next obtained the addresses of lime works in the eastern States through the U. S. Geological Survey Department. In reply to my inquiries they gave most favorable reports, not only stating that phthisis was unknown among their workers, but that coughs and colds seemed to be broken up by inhaling the lime dust. A physician who had medical charge of one of these plants for 40 years, reported that he had never seen a case of phthisis in all those years.

Over and over again we see the question asked: "Why should the dust of coal prevent phthisis?" Why should it? Coal dust can have but one action in the lungs, namely, that of an irritant. It acts like any other foreign body, which is not absorbed by the tissues. In the pages quoted above one is led to believe that coal-dust is beneficial to men working in coal mines. Now when we turn to page 468 we find that employment in coalyards is considered unhealthy. But the dust in a coal mine does not differ from the dust in a coalyard. Consequently there must be something in the coal mine besides coal-dust which prevents phthisis, for it does not prevent it in a coalyard. What is it? We notice too that the older writers report more favorable action from coal-dust than more recent writers. I will tell you why a little later.

To gain further information on this subject I called on two prominent chemists in New York. I told them of my experiments and asked them how they could account for sulphur dioxide in coal mines, for I felt sure it must be present, judging from the results that I had obtained with it in the treatment of tuberculosis. I was informed that coal-dust did not decompose, that it was a stable article, like powdered glass, flint or granite, nor could the body fluids absorb or change it in any way.

To settle this question definitely, I paid a visit to Mr. H. J. Force, the chemist and engineer of tests of the D. L. & W. Railroad Company at Scranton, Pa., on May 2, 1918. His views were no different. I suggested that sulphur dioxide might penetrate through fissures in the coal. I was told that there were no fissures in anthracite. I then hinted that the gas might permeate through the soil. Again I was corrected and reminded that no gases could penetrate, for anthracite rests on beds of clay. The only thing left for me was to ask Mr. Force to analyze the air in a mine under working conditions. This he willingly agreed to do.

On May 20, 1918, he reported the presence of sulphur dioxide in one of the mines. It was due to the sulphur contained in the blasting powder! The air was taken shortly after a blast, and when analyzed showed 17 parts of sulphur dioxide per million of air. The amount of the gas varied according to the number and frequency of the blasts. Very powerful air fans are now used, which was not the case a few years ago. This accounts for the greater immunity in coal mines recorded by older writers. The presence of sulphur dioxide also explains why some cases of pertussis were benefited by visits to the mines.

Some of you here have no doubt read in the *Presse Médicale of Paris*, of January 3, 1918, abstracted in the *Journal of the A. M. A.*, of March 9, 1918, of Dr. Lacombe's remarkable success in the treatment of gonorrhea with sulphur dioxide.

In conclusion I wish to say, judging from my limited experience, that sulphur dioxide will be of benefit in all cases of tuberculosis where the gas can come in contact with the diseased tissues, such as tuberculosis of the lungs, larynx, ear, and nose, also in a certain number of cases of pertussis. This treatment might be given a trial in streptococcic infections and bronchiectases, for the reason that J. and R. J. Reynolds of London reported favorably in these cases with dilute sulphuric acid given by mouth. This might also apply in the various types of pneumonia.

Finally, I believe that sulphur dioxide will be of great value for diagnostic purposes, especially in the early doubtful cases, when there are no physical signs and the laboratory findings are negative. A few weeks treatment can do no harm, and improvement would point to tuberculosis.

The patient with the chronic mastoiditis and the one with dysphagia were present at the meeting. A prominent New York laryngologist testified in the discussion which followed the paper, that he had examined the patient with the tuberculous laryngitis in his office a few days ago and saw two healed ulcers, one on the epiglottis and the other on the left arytenoid, and that the larynx appeared to be getting well.

I purposely omitted details about the use of sulphur dioxide, for when not given in sufficient quantity the results are poor, and when given in excess, the symptoms of the patient are alarmingly aggravated. However, by watching the patient's symptoms carefully the treatment can be given with benefit.

I do not advise the use of sulphur candles, they are too irritating, probably on account of the grease or fat contained in them. The best treatment is obtained with a small tank of liquid sulphur dioxide, which can be obtained in New York from the King Chemical Company. This tank contains about 8 lbs. of the liquid and lasts about eight months. A rubber tube should be attached to the outlet and dipped into a glass test-tube half full of water. In this way the amount of the gas can be regulated.

To begin treatment, select a small room without any metal fittings, as the gas will corrode them. Close all windows and doors. Place the tank in any part of the room, turn on the gas so fast that the bubbles cannot be counted. Within a few minutes the patient will notice the odor of the gas and also taste it on his tongue. Now turn the gas down to about 60 to 100 bubbles a minute, more or less. The patient should stand not less than six feet away from the tank and take deep inhalations, 2 or 3 times a minute, holding his breath at the end of each inhalation for not more than 4 or 5 seconds. Inhalations should be kept up for 15 to 20 minutes at a time. Patients should breathe through the mouth only, except in cases of tuberculosis of the nasal cavities. When there is much sneezing, the nostrils should be closed with pieces of absorbent cotton. Coughing occasionally during treatment will do no harm. When there is much coughing, the gas is too strong; in that case turn it off and open the doors and windows for a few minutes and begin over again, using less gas. The gas is always too strong when it causes weeping or smarting of the eyes.

Inhalations should take place 3 or 4 times a day for incipient cases, and 5 or 6 times a day for severer ones.

When tanks cannot be obtained, the patient can burn a teaspoonful of sulphur on any metal dish by dropping a few drops of alcohol on the sulphur and lighting it. When too much gas is present, the flame can be put out, and when there is insufficient gas, more sulphur can be burnt.

Patients with gastric and intestinal symptoms are much benefited by the administration of dilute sulphuric acid (U. S. P.) mx-xx in a glass of water t.i.d. one-half hour before meals. This causes increased frequency of micturition after a while and should then be stopped or the dose diminished. One of my patients was much benefited by eating raw onions, which I am told contain a large percentage of sulphur.

I shall be glad to give any further information when requested.

An Ancient Canadian Empiric.—Ahern gives an account of a Breton who took up the healing art without the usual process of education. He migrated to Quebec, but since he spoke no French but only the Breton language, nearly starved. In his own sketch of his life he claims to have built up a reputation which extended all over the Province. He practised surgery as well. The death of Yves Phlem, for that was his name, took place in 1749. He left many descendants. According to his own version he received the gift of healing disease from Providence.—*Le Bulletin Médical de Quebec.*

THE MEDICAL TREATMENT OF ENTEROPTOSIS.*

By ANTHONY BASSLER, M.D.,
NEW YORK.

PROFESSOR GASTROENTEROLOGY, FORDHAM UNIVERSITY MEDICAL SCHOOL AND NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; CONSULTING GASTROENTEROLOGIST PEOPLES, BETH-DAVID, STUYVESANT POLYCLINIC, AND CHRIST'S HOSPITALS.

MUCH in a medical way can be done for the enteroptotic individual. To get ideal and substantial results, time, patience, and perseverance are required. There is no quick, easy-to-achieve, and ready-to-accomplish method that answers. In the less severe types relief is easily possible, but in the average case a program must be adhered to for months. It is important for results to consider cases as multisided, and that varying degrees and combinations of conditions are met with, attention to each detail being important to bring results about. Failure in results have come along the lines of considering these people only as those to be given abdominal support, an ample diet, correction of corporeal conditions, and surgery if not successful. The medical side of the work is much deeper than this, and unless one considers the conditions along broader and deeper lines than these the most that can be accomplished medically is not obtainable.

The figures I shall quote are based on a study of 500 cases in my practice, the majority of them persons in good and average circumstances. Careful measurements must be taken of the body and attention paid to developing these to more normal standards. At least 50 per cent. of these were physically deficient. Chest and upper abdomen expansion must be developed by deep-breathing exercises, and they usually have to be taught to breathe infracostally and abdominally. Exercises, of which there are several good systems, are required to build up muscle substance and tone. Most often they must be taught to walk, stand and sit properly, things we have been neglectful of in the past. Ninety-two per cent. had definite posture defects. The gorilla stance must be straightened and the kangaroo bent back until the person walks, stands, and sits so that the vertical weight line runs straight downward through the body, the line coursing from the vortex, through the atlas articulation, the posterior of the rim of acetabulum, and the centers of the knee and ankle joints.

Twenty-eight per cent. had crossed sex characteristics and prenatal stigmata. Here is where endocrinology comes in as a factor for therapeutic results, thyroid excess and suprarenal deficiency making up the majority. For the prenatal stigmata nothing specific can be done, these improving on the upbuilding of the body as a whole. More or less nervous debility and instability are common here, and rest, steady normal routine of life, conservation of the physical and nervous expenditures, and nerve tonics are necessary. I have found that cacydalate of strychnia, the glycerophosphates, and malt extract answer to the best purpose. Depressing social and economic factors were present in 36 per cent. of the cases, and much worth the while can be done in advising them and perhaps changing or modifying their life's main interests. It is in the factors

*Read (by invitation) before the New York County Medical Society, October 28, 1918.

just mentioned that the neurological features come in, and attention must be given to them to benefit the deficient nervous make-up of these people. Ofttimes, if you improve their neurological disturbance, their subjective symptoms, digestion, and assimilation are markedly benefited.

If dilatation of the stomach and colon exists, or distinct disturbances in motility, strychnia, sinusoidal currents, small and often repeated, and high valued caloric meals, would be in order. Usually, the stomach secretions are not markedly interfered with, although the alkalies, oils or belladonna in hyperacidity, or the acids in subacidity, may be called for. When anacidity exists, pancreatic extract may be helpful. The tendency in these cases is for deficient motility rather than hyper. This, in my opinion, is due to deficient innervation to the organ rather than deficiency within it. Therefore, what would help the general make-up of the individual as a whole is the best treatment for the deficient nervous stimuli to the stomach and colon. In other words, if the storage batteries are good and sufficiently charged the wires and organs will respond, and here again comes a neurological feature to the disorder.

All roads lead to Rome, but there is usually a shortest one from wherever you are at the moment; so it is with abdominal support. There are many good ones, but none that are always efficient. We need to support the abdomen between a transverse umbilical line and the symphysis pubis, pouparts ligaments and the front of the crests of the ilea. This support must be upward as well as backward in the line of the mesentery to the root, and some of these people have so little bulk of abdomen to do this with that the ordinarily used support is an ostrich proposition. One can only accomplish this in the slim subject with steels in the front of the belt or corset, steels which have been concaved at the lowest point. I have used this type of support during several years of work, and generally succeeded where others failed.

What I have said as important in the medical handling of these patients is not more important than that the case must be judged in the early instance along two classifications, namely, those who should go to bed and be treated ambulatorily afterward, or not so severe, and can be handled successfully up and about all the way through; and secondly, the intestinal toxemia cases as to whether they are secondary toxemias, and will clean up when the ptosis and general condition is benefited, or whether the intestinal toxemia is primary and will remain to modify the substantial results, and perhaps cause a return of the symptoms in a short course of time.

As to the bed treatment, no benefits in any condition we have to handle is beyond what can be done with these people. The program necessary is replete with details, all of which must be fixedly carried out during three or four weeks' time. In a well-ventilated room, sunny during the day, the bed is raised at the foot from 15 to 25 inches from the floor, the distance depending upon the degree of ptosis. A folded rug is placed between the mattress and spring, or a board transversely across the bed, under the spring and at the level of the hips, keeps these from sagging and the body straight. Only one pillow is allowed, so that the shoulders are kept flat on the mattress, and sitting for eating foods, voiding urine and stool, or reading, is not permitted. Only one hour visiting is allowed during the day, the room is kept quiet, no night reading is permitted, and lights are out at 8 o'clock.

The diet is simple, regular fare being allowed, excepting potatoes, asparagus, Brussel sprouts, cauliflower, highly seasoned foods, made-up dishes, tea, coffee, soups, and broths. No fluid is allowed at the main meals, and interval feedings of fresh cream and water, so that a half pint of double or triple cream is taken each day. The patient should lie on the back for the first hour after the meal, then on the right side. Lying on the abdomen is at no time permitted.

Each day an abdominal massage, finished by general massage, is given. Some simple bed exercises are engaged in and lessons in deep breathing are begun. Small normal saline enemas are given mornings or evenings, and to keep the intestines from becoming too stagnant a dose of cascara once every five days. Belt or corset measurements are taken in the last week and delivered for use three days before the time is up. The patient then gets up slowly, one hour the first day, two the second, four the third, and completely on the fourth. During the first one to three days up they may not feel as well as during the last week in bed, but if mention is made of this they will not become discouraged.

Then they become ambulatory cases, and the program is about as follows: The adopting of the routine mentioned in the beginning of this paper: sleeping in a raised bed for one year; given a diet in which the carbohydrate and hydrocarbons are ample and the native proteins nominal. Water drinking between meals, fruits twice a day, bran, prunes, and vaseline by mouth, are made use of to correct the constipation. This program, dieting, exercises, correction of posture defects, abdominal support, perhaps simple medication, regulation of daily routine, bed up nights, etc., is carried on for months until return of health is brought about.

In my 500 cases, primary or independent chronic excessive toxemia was met with in 50 per cent., secondary, or dependent upon the ptosis, in 24 per cent., and toxemia-free 26 per cent. Therefore, 50 per cent. of all cases have one of the forms of primary chronic intestinal toxemia, and unless this is controlled recurrence of symptoms is very liable to happen in a few months' time. This is the most important part of the treatment of these individuals that is being neglected, and which has brought on so much discouragement in the permanency of results from medical treatment. This field of work requires dieting according to the toxemia present, high protein for the saccharo-butyric, carbohydrate for the indolic, and carefully weighed diet, so there is no excess in the mixed forms. Vaccines are essential to bring results about, these always being autogenous, and used in bold doses, the selection being according as the bacteriology of the gut is off from normal standards. At least 90 per cent. of these most difficult ptosis plus primary toxemia cases are curable by vaccines and diet.

A few of the cases are surgical, but the percentage is small. In people who, because of time or station in life, cannot follow the program outlined, this

number is greatest, and I feel that in them operation may be more freely engaged in. But in the clean-cut enteroptosis case, where proper medical handling can be carried out, my belief is that the medical method of treatment outstrips the benefits possible from surgery, and this is my conclusion from an ample experience with medically treated cases contrasted with a sufficient number treated by surgery. All distinct cases considered, the number requiring surgery represents about 1 per cent. When decided upon, a careful clean-up of angulations, adhesions, bands, as well as suturing the organs in higher position, are required. But even with these it is well to treat them medically for some time after operation has been performed.

21 West Seventy-fourth Street.

CURSORY REVIEW OF MEDICINE AND SURGERY OF THE TWENTIETH CENTURY, VIEWED FROM SEVERAL ANGLES.

By Bittle C. Keister, A.M., M.D.,

Roanoke, Va.

A noted statesman once said: Two things grow better with age, "wine and judges." We may add that the science of medicine and surgery has just as strong a claim for growing better with age, yet requiring more time for development and maturity. In drawing the analogy, we may well say the science of medicine has undergone its stage of fermentation, and, like good wine, it is rapidly ripening into maturity, and with time it will no longer be considered an inexact science.

The present day demand for medical men of proper training and education in the world's greatest epoch, is a strong evidence of the rapid development and usefulness of this great science. Consider, if you please, the 33,000 trained American physicians "over there" doing their bit for liberty and civilization! Consider the important part that science and self-denial on the part of the medical profession is playing in this great world war! The National Research Council is doing much along various lines in the prosecution of this war. Chemistry is solving the problem of absorbing the obnoxious gases to which the enemy has resorted as an unhallowed instrument of torture.

Geology is doing its part in the selection of camp zones and the recognition of adequate water supply. Hygiene and sanitation are important features in the proper management of camp life. The science of physics has solved the problem of detecting the submarines, getting adequate range finders in landing accurately projectiles, improvements in wireless telegraphy, etc., etc.

Among the most important subjects that confronted our scientists in medicine was the food problem. It did not require much time on the part of our National Research Council to discover the deficiency and imminent need of food supplies for our soldiers at the front. As Dr. Lyman Wilbur has aptly stated, a hungry soldier will fight for bread quicker than for the country that is starving him, hence we can readily see the importance of this subject and its bearing on the success of this great world struggle. Our Research Council lost no time in the study of plant and vegetable growing from a scientific standpoint, instilling into the minds of the people patriotic economy, co-operation and food conservation.

Through a campaign of education and patriotic self-denial, the American people are sending this year over 150,000,000 bushels of our wheat to the Allies in starving France and Belgium. These are only a few of the many great things that characterize the magnanimity, beneficence, and usefulness of the great science of medicine as an asset to the world, especially in time of war. If you please, take a panoramic survey of the glorious achievements wrought on the Southern Atlantic Coast during the past decade or so. Go with me down in South America, and as you pass through the great Panama country, the once God-forsaken country, where neither man nor beast could survive but a short period on account of the deadly miasms and other climatic conditions. See what the science of hygiene and preventive medicine has done! With our venerable Dr. William C. Gorgas as the initiator, the death rate from this miasm has been reduced from 60 per cent to only about 2 per cent within the past half decade. Think of the thousands of lives thus saved, and the millions of dollars that have been wisely invested in that once forgotten country! Then, on your return trip, take a passing look at old Cuba, the once hotbed of yellow fever, and observe the handiwork wrought through the instrumentality of our lamented Dr. Walter Reed and of Jesse Lazear, who laid his life down as a tribute to sufferers from this deadly scourge. Our country needs a few more such men as Reed and Lazear in this great epoch-making period of the world.

In the years 1348-50, 25,000,000 deaths from this plague, or "black death" occurred, which was one-fourth of the entire population of the world at that time. In the year 1761, fifty per cent of the English nation died before reaching the age of twenty years. The average length of life in the sixteenth century was only 21 years, while in this, the twentieth century, the average life is 45 years. In India, however, the average life today is only 24 years.

We are thus enabled to see what the science of medicine is accomplishing in our more civilized countries, where ignorance and superstition do not prevail to any very great extent.

It is a well known fact that where these twin curses exist, even in our own much boosted country, especially in the smaller communities where the uneducated negro and foreigner are thickly settled, we may have epidemics of various kinds through the entire year. If we could eliminate from our civilization these twin curses, there would be but little work for the medical man to do.

Dr. Thomas D. Wood, of Columbia University, in a lecture some months ago, made the statement that out of the 32,000,000 school children in the United States, 75 per cent. were physically defective, 1 per cent. mentally defective, 5 per cent. victims of tuberculosis, 5 per cent. with defective hearing, 5 per cent. with defective eyes, 25 per cent. suffered from malnutrition, 25 per cent. had diseased tonsils and adenoids, 50 to 75 per cent. suffered from defective teeth, while 1 per cent. were victims of organic heart disease. Is it any wonder that 29

per cent. of our soldier boys who registered for the great world's war were rejected on account of physical disability? In some of the States of the Union from 50 to 75 per cent. were rejected on this account.

The United States is today expending four billion dollars annually toward the prevention of diseases that are preventable, and that have their origin primarily from the two causes above mentioned, ignorance and superstition.

We may take that fell disease cancer, about which we know so little, and which is today destroying 500,000 persons annually. One of our fellow mortals is giving up his life to this monster enemy every six minutes. One in every twelve of our men, and one in every eight of our women, die from this disease.

What I have stated about cancer applies with equal, if not greater, force to tuberculosis and pneumonia. According to the latest statistics, there are today 8,000,000 people in the United States who are destined to die of tuberculosis; 175,000 persons died of this disease last year; 1,500,000 people are incapacitated annually in the United States from this disease. The toll exacted by tuberculosis throughout the world is about 144 human lives each hour. In China this white plague takes a person every 37 seconds. In Japan every two minutes, and in India about the same proportion of victims exists. These figures vary in different countries, according to the degree of civilization and education.

You will observe we are viewing our subject from various angles, and, while we may congratulate the great science of medicine and her corps of energetic laboratory workers on past achievements, yet there is much to do, and it behoves every medical man to buckle on the armor of war and face these deadly enemies of the human family which are today destroying more lives and are a greater menace to our country than were all of the Central Powers of our European enemies during the great war.

In view of these stern facts confronting our much boasted civilization of the twentieth century, is it not high time for our Federal Government to take due notice of the situation by placing a suitable medical man in the Cabinet at Washington as Secretary of Public Health and Preventive Medicine?

But let us take courage from the example of our predecessors in medicine in making our fight against the above mentioned "Triple Alliance" of cancer, pneumonia, and tuberculosis, that are destroying our race like the despotic Huns, regardless of age, sex, or nationality. Let us give more study and research to the cause of disease and the many deadly infections, and do as the great pathfinders, Jenner, Holmes, and Lister did, put into practice our findings. Undying credit is due Lister for his bold stand in putting into practice his discovery of a paste that revolutionized the surgical practice in the treatment of wounds.

With all due deference to antiseptic preparations and their distinguished discoverers however, as well as their many advocates, after a quarter of a century of active work in all lines of surgery and preventive medicine, I am still an advocate of the pre-war practice of asepsis, using only sterile applications in fresh, clean wounds, and germicidal applications only in old or pus wounds. I am glad to see the pendulum of radical surgery is rapidly receding, allowing conservatism to play its part, hence the less need of antiseptics, but the greater demand for the exercise of common sense, cleanliness, and surgical prevention.

When treating an old pus wound outside of a hospital, I would just about as leave treat it by a modified Lister method as the more modern Carrel-Dakin method. But for sure results, I would, in such cases, fall back on an old standby, namely, one part iodoform, two parts bismuth subcarborate, in sufficient quantity of sterile vaseline to make a paste or ointment, and enough thymol or eucalyptol to disguise the iodoform odor. With thorough cleanliness prior to making this application at proper intervals, any ordinary wound, other things being equal, should heal readily. The simplicity of this method should commend it, especially when we consider the extraordinary virtues of iodoform in rendering the soil inimicable to the growth of the germs, thus starving them in their own habitat, and preventing their migration to other fields. This commendable feature is worth considering when comparing it with bichloride and other antiseptics that act only as antiseptics, leaving the soil or habitat in an irritable or favorable condition for the growth and diffusion of a second or third regiment of microbes.

While we are paying tribute to our pioneers in surgery, the men whose business it was to handle the knife, we should not forget the noble men who made it possible to "cut without causing pain." With true Southern pride, we may modestly refer to Dr. Crawford Long as the real discoverer of sulphuric ether, while according an equal amount of glory to Dr. William G. T. Morton, a dentist by profession, who deserves the honor of making sulphuric ether practical as applied to surgery.

The first public demonstration made in a surgical amphitheater took place in the Massachusetts General Hospital on Oct. 16, 1846, when Dr. J. C. Warren performed the first surgical operation with the use of ether, administered by Dr. Morton, on a patient by the name of Gilbert Abbott. The operation consisted in the removal of a congenital tumor from the left side of the neck, extending along the jaw to the maxillary gland and into the mouth, embracing the margin of the tongue. The operation was successful, and when the patient recovered he declared he had suffered no pain. After completing the operation Dr. Warren turned to those present and said: "Gentlemen, this is no humbug." Unfortunately, Dr. Morton sought to establish his claim as the real discoverer of sulphuric ether and to secure a patent on same, and this, coupled with the bitter contention and disloyalty of his once trusted friends, led to his downfall and death in poverty at the early age of 49. Had he acted throughout as did Dr. Crawford Long, the real discoverer of sulphuric ether, no doubt but it would have been far better for him, as well as more comforting to his friends.

Dr. Long was born in Danielsville, Ga., and was known as a modest country practitioner, far from the centers of medical learning, and destitute of means sufficient to exploit his great discovery. He did not at the time realize the importance of the discovery, the vast benefit it was destined to bring

to the relief of suffering humanity. During the month of January, 1842, Dr. Long commenced experimenting with his new vapor, by allowing frolics to be held in his office by young lads who delighted to inhale the fumes of this exhilarating substance, some of them getting drunk and staggering about, knocking themselves against tables and other furniture without experiencing pain. This Dr. Long noted with special interest, and decided then and there, when opportunity presented, to make use of this new agency for the relief of pain.

On March 30, 1842, he operated on a man named James Venables, removing a small cystic tumor of the jaw with success and without the least pain. This success was followed by other operations in minor surgery by Dr. Long, and in the latter part of the year 1842, he presented a paper before the State Medical Association of Georgia, describing the effects and his results in the use of this new vapor that he had been experimenting with. Dr. Long did not push himself into the arena as a claimant for the honor of the discovery of anesthesia until 1854, when he felt it his duty to keep silent no longer, since such an array of claimants as Morton, Jackson, Wells, and Marcy were eagerly clamoring for the plum that rightly belonged to him.

We might give equal honor to Doctor Dumas of Paris, France, for the discovery of chloroform. I have dilated somewhat at length on this part of my subject, because of the great benefit of these discoveries to suffering humanity, not only for the past three-quarters of a century, but for all time to come. Then the close relation these discoveries bear to medicine and surgery makes it worth while to cherish the memory of these noble pathfinders. Then all honor and glory to Crawford Long for the discovery of sulphuric ether, to Morton for making it practical in surgery, and to Dumas for the discovery of chloroform! These two anesthetics alone have done more toward relieving the sufferings of the world than all other combined agencies. Every mother on the two hemispheres, if requested, would place a wreath of the purest and whitest flowers, bound by the threads from her own sacred locks, on the graves of these three noble benefactors. It would be but a fitting tribute if every surgical and lying-in hospital in the whole world would place a memorial tablet of the purest bronze on the walls of their operating amphitheaters.

We will now treat our subject, as stated in the outset, from another angle, namely: the attitude of the medical profession of the twentieth century, viewed from the standpoint of civic betterment and altruism.

Has the standard of the medical profession, like wine and judges, grown better and nobler with age? This question may be answered from one angle in the affirmative, and from another angle in the negative. From a scientific standpoint, including equipment, better facilities, and all that constitute a modern science, in both medicine and surgery, the answer, as previously intimated, is quite evidently in the affirmative. But whether the standard and altruistic spirit of the twentieth century medical man is on as high a plane now as a century or more ago is very questionable.

When we recall the self-sacrifice and the altruistic spirit that characterized the motives of Edward Jenner, Oliver Wendell Holmes, Joseph Lister, and many others, and draw the comparison with some of our moderns, we cannot help feeling a sense of humility. In making this comparison of the present and past, I include the entire globe where the medical profession is recognized, but would lay special emphasis on these conditions as applied to the United States.

Consider the commercial spirit that pervades the medical profession to-day, the anxiety for filthy lucre, which, to a great extent, obscures the beauty, the grandeur, and honor of the real science of medicine which was maintained and held so sacred by our ancestors. Think of the men who are following the phantoms, the ignis-fatuus of the present day, under the guise of cancer and consumption cure-alls, who are more interested in the shekels that are pouring into their coffers than they are in the diseases that they claim to cure. They do not heed the warnings of science and surgery, but go on exploiting their cure-alls, regardless of the fraud committed on their innocent victims.

Then if you will permit, let me remind you of a far greater stigma that hangs over our noble profession as a twentieth century pall. We gather from reliable statistics and good, authentic source that 33 per cent. of the medical profession of to-day are narcotic fiends. I challenged this charge by writing the party that made the statement, and after some correspondence I had to acknowledge the correctness of the accusation. In this accusation, however, alcoholic beverages were included under the head of narcotics. I also found that the other learned professions were included in these startling statistics. I am making these bold statements with some degree of trepidation, yet they are facts that cannot be refuted, even though they are not so pleasing to our sense of pride.

It has become a much-mooted question of late years, and is to-day being discussed by some of our most able thinkers of the medical profession, as to whether our profession and our patients would not be better off without the use of the common narcotics, especially those that belong to the habit-forming class. We have very scant account of this class of drugs being used by our ancestors of a century ago, and it does seem strange that if they, with their limited armamentarium and the many other handicaps with which they had to contend, could do without them, we of the twentieth century enlightenment could well afford to eliminate them from our pharmacopeia.

In looking over the weekly death list of our colleagues, college mates, etc., we are struck with awe in noting so many sudden deaths, suicides, and premature deaths. Why so many of these in our ranks ere the three-score and ten limit is reached, when so many of our ancestors passed over this limit? When we consider our present day advancement in the science of medicine and surgery, and the many adjunct facilities for the successful treatment of diseases, the superior hospital advantages with better trained nurses, etc., we may well ask, Why such a high rate of mortality in the medical profession? Oliver Wendell Holmes maintained his mental and physical vigor until he was 84 years old, which was a clear gain of 14 years over the allotted time for man to live. This may be accounted for,

in part, as due to his temperate habits, his cheerful and jovial disposition, notwithstanding the fact of his many trials and the strong opposition and severe criticism by his own medical brethren of his famous essay on puerperal fever, and his stand on the management and care of the lying-in expectant mother. Dr. Holmes was an all-round developed medical man, hence free from the petty jealousies, worries, etc., that characterize the lives of so many of our medical men of this commercial age. It has been wisely said that cheerfulness and contentment play a large part toward a medical man's success as well as toward enabling him to reach the goal of three-score and ten years. When we consider the longevity of our ancestry in the medical profession, these facts become very important and worthy our careful thought and meditation.

It was the privilege of the writer to listen to a very interesting paper read by Lister at the International Medical Congress held in Paris in 1900. Lister had then reached the age of three score and thirteen, and his clear voice and erect figure, military step, and handsome physique all indicated to the writer that he was good for another score of years. He had been a hard worker from the time of his graduation in medicine, but he never failed to observe the first law of nature, "self-preservation." There was less of the spirit of commercialism and personal jealousy in former times than we see at the present day. A lawsuit for malpractice or damages was almost unheard of, while at the present day we scarcely pick up a newspaper without seeing accounts of malpractice suits against some member of the profession. In fact, it has become so obnoxious that a medical man of any means or one who has charge of a hospital in his own name is forced to carry a liability insurance policy as a protection from the shylocks. Strange as it may seem, we have men in the profession who are low enough to lend their influence and testimony to this class of lawyers for a mere pittance or for their traveling and hotel expenses, regardless of the merits of the case. Usually lawsuits are due to some form of grievance or misunderstanding and a desire to gain something by fraud, and when you find a physician allowing himself to be a witness against a worthy brother physician in a suit for malpractice, in nine cases out of ten you will find that there has been an old grievance existing between them, or he is actuated by prejudice. Such men are a menace to our profession and should be debarred from membership in any State or county medical society, regardless of their standing as expert surgeons or specialists. It has become a most commendable feature in many of our State and county medical societies to establish and maintain a board of censors for the express purpose of defending its worthy members from these lawsuits. Why cannot all State societies introduce this commendable feature as a part of their work? No stronger inducement could be offered to increase the membership of the county medical society.

You can readily infer from the foregoing that in the writer's judgment the moral standing and the altruistic spirit of the medical profession of to-day does not rank on as high a plane as it did in the days of Jenner, Holmes, and Lister. In scientific attainments, however, it leads.

It behooves the medical profession of to-day to begin to take notice, and if possible inculcate some of the humane and altruistic principles that characterized our forefathers in medicine, and thus retrieve some of our lost prestige. Our medical faculties could do much along this line by putting a little more of "the personal" in their lectures to medical students, instead of requiring them to work out their own salvation with fear and trembling.

The whole medical profession, including the medical faculties of our colleges, could profit both materially and socially if we would put into our daily lives a little more personal and social spirit. Our influence over the laity as well as over our colleagues would be felt in more ways than one. It is the duty of every medical man to cultivate the spirit of sociability, without which accomplishment his financial income, like his popularity, wanes with each passing decade of his professional life.

22 Day Avenue, S. W.

THE VALUE OF SACCHARIN AS A FOOD IN DIABETES.

By W. E. BURGE,

URBANA, ILL.

OF THE PHYSIOLOGICAL LABORATORY OF THE UNIVERSITY OF ILLINOIS.

In diabetes it is known that oxidation is defective, as is indicated by the fact that the diabetic is unable to burn sugar, and because of this inability to use sugar, saccharin, which is five hundred times as sweet as cane sugar, has come to be used very extensively as a sweetening agent in the food of people suffering from this disease. The object of the present investigation was to determine if saccharin has any value in diabetes other than as a sweetening agent. Neubauer,[1] Benedict and Török,[2] Allen and Du Bois, have shown that the administration of alcohol and alcoholic beverages, such as red wine and whiskey, facilitates the oxidative processes in diabetes, thereby enabling the diabetic to burn sugar better, with resulting decrease in acidosis and sugar excretion. We[3] have shown that catalase, an enzyme in the tissues possessing the property of liberating oxygen from hydrogen peroxide, is decreased in diabetes, and accordingly suggested that the defective oxidation in this disease is due to the decrease in catalase. We[4] have also shown that the administration of alcohol increases catalase by stimulating the digestive glands, particularly the liver, to an increased output of this enzyme, and hence attributed the helpful effect of alcohol in diabetes, as suggested by the work of the men named above, to this increase in catalase. Moreover, we have found that whatever increases or decreases oxidation in the body produces a corresponding increase or decrease in catalase, and hence the conclusion was drawn that catalase is the enzyme in the tissue principally responsible for oxidation.

Stated more specifically, the present investigation was begun to determine if saccharin stimulates the digestive glands, particularly the liver, to an increased output of catalase, thus facilitating oxidation in diabetes, as is done by alcoholic beverages. Dogs were used in the investigation. These animals were rendered diabetic by the removal of the

pancreas. The saccharin used was "soluble saccharin" prepared by adding one-half part of sodium bicarbonate to saccharin. The amount administered was four grams per kilogram of body weight. Herter,[5] in his investigation for the Referee Board on Saccharin, gave this amount to rabbits without evil effects. Previous to the introduction of the saccharin into the stomach and intestines of the animal a determination was made of the catalase of the blood taken from the jugular vein. After the introduction of the saccharin determinations of the catalase of the blood taken from the same vein were also made at intervals of fifteen minutes. The determinations were made by adding 0.5 c.c. of

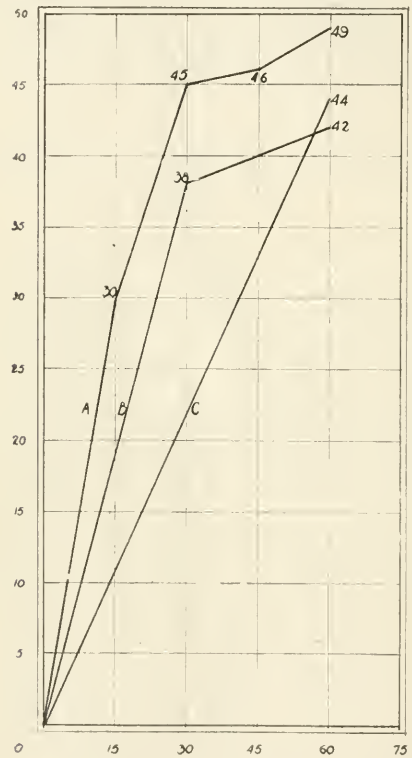

Fig. 1.—Curves showing percentage increase in catalase after the ingestion of saccharin. The figures (0-75) along the abscissa indicate time in minutes and the figures (0-50) along the ordinate percentage increase in catalase.

blood to 50 c.c. of hydrogen peroxide in a bottle at 22° C., and as the oxygen gas was liberated it was conducted through a rubber tube to an inverted burette previously filled with water. After the volume of gas collected as described in ten minutes had been reduced to standard atmospheric pressure the resulting volume was taken as a measure of the amount of catalase in the 0.5 c.c. of blood. The material was shaken in a shaking machine at a fixed rate of one hundred and eighty double shakes per minute during the determinations.

Curves A, B, and C in Fig. 1 show the effect of the administration of saccharin to dogs which had been rendered diabetic by the removal of the pancreas. The figures (0-75) along the abscissa indicate time in minutes and the figures (0-50) along the ordinate indicate percentage increase in the catalase of the blood. It will be seen that the administration of saccharin greatly increased the catalase of the blood, the greatest increase, which was 49 per cent., being in the blood of the dog from which data for curve A were obtained. From the standpoint of calories, saccharin cannot be regarded as a food, since it is not oxidized in the body; but from the standpoint of producing an increase in catalase, thereby facilitating the oxidation of the other food materials, it is even more effective than fat or carbohydrate, and equally as effective as protein.

From the results of the experiments reported in this paper the conclusion is drawn that saccharin, in addition to serving as a sweetening agent, serves to facilitate oxidation, and hence should be positively helpful, particularly in a disease such as diabetes, where the principal trouble is defective oxidation, instead of harmful, as some have claimed.

Medicolegal Notes.

Medical Expert Testimony—Use of Medical Works as Evidence.—In an action for malpractice there was evidence tending to show that the plaintiff was in an automobile accident and suffered a simple fracture of the middle third of the right femur. He was taken to a hospital in Newport, where he was attended by the defendant and another physician, Dr. Blanchard. These two doctors, with other assistance, set the leg, making use of a Liston splint. Both doctors attended the plaintiff for a time, and the defendant attended him until he was moved to his home in Irasburgh, on December 20, 1913, which was about three weeks after the accident. Two days after this removal the defendant visited the plaintiff professionally at the latter's home, and once later saw him at Irasburgh when he was there to visit another patient. On January 15, 1914, Dr. Templeton, who was then caring for the plaintiff, removed the splint and found the injured leg 2¼ inches shorter than the other one. This condition was permanent, and the ends of the broken bone overlapped so that there was angular conformity at the point of fracture. The result caused pain and discomfort and interfered with his ability to handle his business of traveling salesman.

The plaintiff called the defendant to the stand and examined him as a witness. When he was questioned by his own counsel he was asked what medical authorities prescribed the method of reduction and treatment used by him on the plaintiff; and without objection he replied that Walsham was such an authority. Thereupon his counsel produced a book entitled "Surgery, Its Theory and Practice," by the author named, and asked the witness if the book, on pages 445 and 446, exactly described the method so used by him. This question was excluded and the defendant excepted. The Vermont Supreme Court holds that the exclusion was correct. That the contents of the book were not evidence of the facts therein stated is shown by Rogers v. State, 77 Vt. 454, 61 Atl. 489, and many other cases in other

states. And it was held improper, in the circumstances here existing, to ask a medical expert if he is acquainted with a certain book, and, calling his attention to a particular paragraph, to ask a question in the language of the book, and thus indirectly introduce such passage in evidence. The suggestion that the evidence would corroborate the witness is without force. It is not permissible to reinforce a witness in this way.

It was held there was no error in the cross-examination of Dr. Stockwell, an expert witness for the defendant. In his direct testimony, referring to the method used by the defendant, he asserted that it was a treatment recognized by the best authorities. In cross-examination he was very properly asked to name the authorities thus referred to, and replied that Walsham was the one he most relied on, and that Stimson spoke of this method. Thereupon the witness was asked if Stimson did not say that treatment by weight and pulley or elastic traction was almost exclusively employed in such cases, and, subject to exception, the witness replied in effect that he did. The court thought it apparent that in his first statement the witness intended to have the jury understand that Stimson approved the Liston method of treatment. It was therefore proper cross-examination to show by the book itself that the author did not approve such treatment. While it was not permissible to read the book into the case for the mere purpose of showing that the author disagreed with the witness, it was permissible to contradict and discredit him by showing that the book did not warrant his statement.

Dr. Young, another expert for the defendant, testified in direct examination that the Liston method was well recognized by the authorities. He also testified in cross-examination that he had observed that there was usually a great deal of pain from the use of Buck's extension. Thereupon counsel for the plaintiff asked the witness if Scudder on Fractures, a recognized authority, did not say that, as a general rule, the use of Buck's extension was followed by very little pain; and he was shown the book to refresh his recollection. This was objected to by the defendant, but the objection was overruled and the answer taken subject to exception. The Supreme Court holds this was error. It was not competent to contradict the witness in this way. As to the matter of the pain incident to the use of Buck's extension, the witness spoke of his experience and observation only, and made no reference, directly or indirectly, to Scudder or any other medical authority. His standing was entirely different from that of Dr. Stockwell, who spoke wholly of what the authorities approved. And right there, the court said, lies the distinction. When an expert witness testifies to his own experience and observation only, authorities cannot be read into the case either directly or indirectly on his cross-examination. But when he testifies as to what the authorities show, or bases an opinion in whole or in part upon what they advocate, the books may be used to contradict the witness and to discredit his testimony, though he mentions no particular author.

Just when and how far these books can be used to test the qualifications of the witness the court did not inquire, as the record showed that this ground of admissibility, if otherwise available, was excluded by what was said and done below. But this error was not made to appear harmful. When the answer of the witness was complete, it appeared that all the author said was that "ordinarily there would be little or no pain associated with the repair of the fracture," without a word about any particular method or apparatus. The defendant had already admitted that Scudder made this statement, and under any rule and in any case the error was harmless.

Dr. Templeton, testifying for the plaintiff as an expert, said that when a leg was put up as this one was, and severe pain continued at the point of fracture, it indicated that the dressings were too tight at some place, or the parts were not in apposition. So far no objection was made. He was then asked what could be done in a case like this, and, subject to exception, replied that a careful examination of the injured parts should be made. The court overruled this exception, since it was so obvious from the testimony that such an examination should be made in the circumstances stated that the answer could not have prejudiced the defendant.

During the cross-examination of Dr. Templeton he testified that the books approved of various methods of securing the requisite extension, counter extension and fixation in such fractures as here involved, but that he had never observed an approval of the use of a splint of the character of the one used by the defendant, though he had read of it in obsolete works. He was then shown a copy of Stimson on Fractures, published in 1900, and he testified that he never heard of it before, and knew nothing about it as an authority, but should not call it obsolete. He was then asked if he noticed that among the dressings therein prescribed was a side or hip splint usually with traction. This question being objected to, was excluded, and the defendant excepted.

The object of this inquiry, as stated by counsel, and as shown by a formal offer, was to show the fact that the author approved this kind of a splint. But later on in the trial the passage referred to was read to Dr. Lange, and all the benefit therefrom asked for by counsel was obtained. Thus the error, if any, was rendered harmless.

Dr. Aldrich, an expert witness for the plaintiff, testified that he had never used or seen used a Liston splint, and knew nothing regarding results of that method of treatment. He was shown two *x*-ray plates which were exhibits in the case, and asked whether, assuming the plates were taken of the plaintiff's injured leg, the angular deformity shown was such as would be produced by bandaging the leg to the side splint as was done by the defendent; and, subject to exception, he was allowed to answer that it was. The defendant argued that this was error, because it was allowing the witness to usurp the province of the jury by expressing an opinion on the very question the jury was to decide. But the court said it is not at all unusual to allow an expert witness to give an opinion that a particular condition is due to a specified cause. The fact that Dr. Aldrich had never had experience with this method of treatment did not disqualify him as a witness.

Dr. Kendrick was another of the defendant's experts. He testified that he had used a Liston splint in three cases; that Dr. Stockwell assisted in one of the cases, and Dr. Cushman in another. The trial court declined to allow the witness to say whether they approved the method adopted by him. This ruling was held without error. There approval could only have been indicated by what they said, or possibly by what they did, on the occasions referred to. The offer, at best, was a mere attempt to show what those doctors then thought about the propriety of that method. This would be nothing but hearsay. Both the doctors were in court, and were witnesses in the defendant's behalf. As such they approved the defendant's method of treatment and gave him the benefit of their present opinion of it. That they entertained similar views at some previous time was immaterial.—Baldwin v. Gaines (Vt.) 102 Atl. 338.

Misjoinder of Defendants.—The Mississippi Supreme Court holds that a complaint alleging that deceased, an employee of defendant railroad, was required to contribute to the maintenance of defendant hospital, which employed defendant physician, and that, when injured, the deceased was taken to the hospital, and as a result of malpractice of the physician and negligence of the officials of the hospital he died, did not state a cause of action which was joint and several, but was demurrable, since it was based on contract as to the railroad and on tort as to the other defendants, whose liabilities were not the same.—Owens v. Gulf & S. I. R. R. Co. (Miss.) 79 So. 248.

Sites for Sanatoria in Residential Districts.—The New York Supreme Court, Special Term, New York County, holds that where the refusal of the board of health of a city to approve as a site for a sanatorium property in a residential neighborhood is based on its effect on values of adjoining real estate, mandamus to compel approval will be granted. The court holds that Greater New York Charter, section 1,172, providing that boards of health, whose jurisdiction is confined to matters of public health, may embrace in the Sanitary Code all matters to which the authority of the board extends, "not limiting their application to the subject of health only," limits the jurisdiction to matters dealing directly or indirectly with the public health and life.—People ex rel. Sprenger v. Department of Health, 172 N. Y. Supp. 38.

Military Medicine.

The Emergency Treatment of Gunshot Wounds.—If circumstances permitted, the healing of infected gunshot wounds could be greatly promoted by excision during the pre-inflammatory period, *i.e.* within twenty-four hours of the receipt of the injury. It has been amply proved during the present war that excised wounds will often heal by primary union, and even when this result is not obtained the more serious consequences of infection will be prevented by the early institution of this measure. Lieut.-Col. Hill, R. A. M. C., writing on this subject in the *British Medical Journal*, notes that the success or failure of treatment of gunshot wounds depends largely upon the stage at which the wound comes under treatment. During the first few hours following its infliction a wound is comparatively clean, judged by bacteriological tests. The organisms have not had sufficient time to multiply in order to appear in the secretions. At the end of five or six hours organisms are frequently found in smears, and after twelve hours the wound has commenced to react. Bacteriological examination shows a large number of organisms, and these have now spread to the depths of the wound. It is, therefore, during the first twenty-four hours that the wound is amenable to surgical treatment, for after that period an inflammatory stage appears, during which the results of excision have been very much less satisfactory.

The question now arises whether it is possible to prolong the pre-inflammatory stage. The only treatment which a wound at present receives in war previous to being excised or otherwise dealt with at a casualty clearing station is the application of a first field dressing, the depths of the wound receiving no treatment. In fact, in spite of the advances in surgery, particularly in the treatment of wounds, the emergency treatment is no more efficacious than it was in the days of the Trojan wars. Since the old first field dressing appears to be totally inadequate, it has been suggested that, as soon as practicable after the infliction of a wound, it should be instilled with some non-irritating antiseptic, in order to inhibit the growth of microorganisms. When septic foreign bodies are retained in a wound, the growth of organisms would be enormously retarded by the presence of an inhibiting antiseptic. Septic cloths would become soaked with the reagent injected, and would become comparatively innocuous. Excision of the wounds could be carried out in due course with greatly enhanced likelihood of primary union.

Several reagents which are non-irritating inhibitors of septic organisms are available. Flavine in 1 in 1,000 solution or dichloramine-T would appear to be suitable anticeptics for the purpose. Brilliant green is frequently used (as recommended by Captain Hey) as an anticeptic stain. The wound is filled with brilliant green, which acts as a guide to infected tissue, previous to the excision of the septic area. This reagent would fulfill a double purpose if instilled into the wound at an early stage, by acting as an inhibitor of sepsis, and a guide to the septic tissue. Dakin solutions are too evanescent and too transient in their action for this purpose—as, in fact, they are for any wound treatment during transport. If a 5 per cent. solution of salt be combined with the antiseptic reagent, the microorganisms will not only be inhibited in the wound, but an outpouring stream of serum will be produced which will carry infection from the wound, and prevent the ingress of organisms.

The technique of wound instillation is of the simplest possible description. The chosen solution is instilled by means of a fine glass nozzle attached to a Higginson's syringe, care being taken to inject fluid into the depths of the wound. There is indication for the use of this method in casualty clearing stations. In times of pressure a patient may have to wait a day or more before an operation can be performed. The preliminary instillation of the wound with an inhibiting antiseptic solution may make the difference of the wound being operated upon in the pre-inflammatory stage, or when suppuration has commenced. Still more desirable is such treatment when it is necessary to transfer a patient to the base from casualty clearing stations without operation. By beginning wound instillation within an hour or so we are treating a wound which is bacteriologically as sterile as an excised wound, and but for the tissue necrosis which follows gunshot wounds the early instillation of a suitable antiseptic might replace wound excision.

The New German Methods of Antisepsis.—Voncken, in the *Archives Médicales Belges* for October, 1918, makes a brief contribution with the above title, and as subtitle "antisepsis or asepsis." Some of the pathologists beyond the Rhine are evidently looking forward to a return to asepsis on a peace footing. Whatever their utility in war surgery the fact remains that antiseptics not only injure the integrity of the cell but often do not destroy the germ life in wounds. The triumph of antisepsis is no doubt brief and the bactericide remedy will go into the discard—in fact the more a substance is bactericidal the more is it to be shunned as inimical to the organism. Chemotherapy in other words is not rational. Certain methods, like the Dakin irrigation, cannot stand criticism because if antiseptic at the start their power of this sort is soon forfeited and if the solution still is active it is only because of antitryptic properties which are indirectly hostile to germ life.

Certain German writers speak of deep antisepsis and this resource is meant to supersede the Dakin irrigation which is of course superficial in its activity. Under this head comes the internal use of hexamethylenamine. This substance is changed in the organism to formal, which can be recovered from the wound secretions. The objections to the constitutional antisepsis are two; it is founded on theory alone and its results in practice are not startling. Better grounded is the practice of deep injections around a wound area—a sort of antiseptic barrage. Bier began this method in the case of acute abscess. After the evacuation of the pus the abscess wall was injected with ethyl hydrocuprein. As this worked well he extended the method to suppurating

joints, but without duplicating his success. In gas abscess and gangrene as a prophylactic, ethyl hydrocuprein has been used freely. In reply to the query, "Are not such substances also antiseptics in the ordinary sense?" the answer would be in the negative. While they indeed have power over bacteria they are absolutely innocuous to the tissues and do not in any way interfere with normal cell life. Ethyl hydrocuprein, according to Morgenroth and others, may be destined to revolutionize surgery so far as laboratory experience may foreshadow the outlook. But there has been no lack of adverse criticism. The claim has even been made that while its action on a mere abscess is all sufficient it is not only helpless but dangerous in diffuse suppurations. Other surgeons, following those in the Allied Armies, teach extirpation of a wound focus with immediate suture. Deep antisepsis with quinine and copper derivatives has been tested freely with the aim of preventing the extreme mutilation and sacrifice of tissue and the resulting crippling. Ansinn, a surgeon of Munich, has devised a special technique for the deep peripheral injection of recent wounds. Voncken, however, is unable to state whether or not the method has been tested thoroughly and if so, whether it has made good.

In the meanwhile the intravenous method of antisepsis has had a tryout. The possibility of a venous infiltration of the tissues in a given area was long ago shown. In wounds of the extremities an Esmarch bandage renders the limb bloodless, and compression leaves the member anemic. A vein is then dissected out and made to serve for injection. Laboratory experiments show that the diffusion of various injected solutions is complete. The quinine synthetic already mentioned was used in this manner for gonococccic arthritis and tuberculous foci in the extremities were treated with tuberculin intravenously, while the method was also tested in syphilitic lesions with salvarsan. In such affections the results were disappointing. In military surgery the method has also been tested in gangrene and pyemia, but there are special technical difficulties here due to the nature of the drug injected. For this or other reason the method is not promising and from the theoretic viewpoint arteries and not veins should be the proper vessels for injection. Whatever the future success of the method, a question will be raised as to whether it is antisepsis or asepsis. The benefit to accrue from the quinine may be only a stimulation to leucocytosis or other biochemical property.

Influenza Deaths in Camps.—An official summary of the results of the influenza epidemic in army camps and military centers in the United States, made public by the War Department on December 10, shows that there were 338,257 cases of the disease up to December 1, with approximately 17,000 deaths. From September 13, the date of the outbreak, to December 1, 19,694 deaths from all causes were reported by military stations in the United States; about 2,000 of these deaths were due to causes other than influenza and pneumonia.

Navy's Influenza Tests Negative.—According to a report recently made public experiments undertaken by the Navy Department at the Navy Public Health Service Hospital on Gallupus Island, Boston, to ascertain the cause and reasons for the spread of influenza have had merely negative results. One hundred men volunteered for the experiments and it is stated that they had influenza germs placed in their nostrils and throats and swallowed them with their food, and some were inoculated with serums. The investigation has afforded no definite information as yet. The tests will be continued.

Peace News Cures Shell Shock.—Surgeon General Ireland is reported to have told the Senate Military Committee that more than 2,000 American soldiers in France who were suffering from shell shock were cured by the news of the signing of the armistice.

Red Cross War Work.—Details of the Red Cross work during the war show that the organization spent $22,114,209 in France, $16,964,048 in Italy, $8,458,516 in Russia and Siberia, $2,285,672 in Switzerland, $2,714,610 in Roumania, $5,118,505 in Palestine, $10,830,250 in England, and $3,379,699 in Belgium. Total home service expenditures amounted to $6,000,000, with an equal amount spent on cantonment activities. Up to June 30 last, the convalescent home service work had cost $1,512,000, with another $1,000,000 appropriated for it for the six months ending December 31. The Red Cross has approximately $13,000,000 worth of supplies on hand in France for future use. Finished supplies valued at $59,000,000 made by Red Cross workers all over the country have been turned out during the last seventeen months. It is estimated that during this time some eight million volunteer workers have turned out 253,196,000 surgical dressings and 22,255,000 articles for use in hospitals as well as over fifteen million knitted articles and garments for relief work.

The Annual Report of the Surgeon General, U. S. Army, for 1918 (including statistics for the calendar year 1917 and activities for the fiscal year ending June 30, 1918) has just been issued from the Government Printing Office. It contains a comparative study of the health of the Army, 1820-1917; an account of the health of the mobilization camps and of the Army by countries; a consideration (70 pages in extent) of the principal epidemics in the camps; and a discussion of fractures and operations. Nearly 200 pages are devoted to the special activities of the medical department — with the American Expeditionary Forces, and in the divisions of sanitation, hospitals, supplies, laboratories, and infectious diseases, internal medicine, general surgery, orthopedics, head surgery, neurology and psychiatry, psychology, food, and the Dental and Veterinary corps. In addition to the usual tables of illness, discharge for disability and death, there are given tables of battle wounds and operations; of complications of various diseases and of case mortality. The text is illustrated by 73 charts. Altogether the report is a study of health and morbidity in an army of over 1,500,000 men, for the most part yet in the period of training. It should be of interest to epidemiologists, vital statisticians, and army medical men.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

PARIS EPIDEMICS OF THE XVI CENTURY.

As a contrast to what New York encounters in the current decades one may read with interest of what was going on in Paris three centuries ago. Early in the XVI century the "pest" scourged the metropolis 70 years before the influenza is said to have appeared under the term coqueluche (now limited to whooping cough). But according to Paré this malady had already manifested itself in 1510 and was even then termed by the people coqueluche, with all the symptoms of influenza. The latter had many victims among rich and poor. The question arises, was this epidemic of 1510 a plague or grippe or did both appear in Paris contemporaneously? In 1519 the pest had not left Paris and assemblages of people were discouraged. In 1531-3 the pest was again prevalent and with the public fully possessed if not obsessed with the idea of contagion, the precautions ordered could readily have been exaggerated. Every possible avenue of contagion, direct or mediate, was respected. In 1561-2 a new plague appeared under the name of lues pestifera. The correspondent of *Le Progrès Médical* for October, from whom the above citations are taken, furnishes no clinical data for these outbreaks and prophylaxis centered on isolation of pest houses and inmates and destruction of substances proceeding from such houses. Another epidemic in 1578 was like dysentery or a choleriform affection. In 1580 occurred the epidemic which passes in history for the first Parisian experience with modern influenza.

The word coqueluche was one of several similar names for a headdress and was believed to have meant in the vernacular headache, and an epidemic in which the latter was the most striking symptom. The phenomena of the coqueluche agreed in all respects with the leading symptoms of influenza. Its contagiousness was so great that but a small fraction of the people escaped. But no one seems to have perished from the malady. It passed over the city rapidly but was soon followed by an epidemic termed the pest which required the intervention of the State in erecting temporary pest houses. Finally in 1596 another visitation appeared which killed many people with "pleurisies." It is evident that two pandemics occurred under the names pest and coqueluche, the latter answering to influenza while the former, probably bubonic plague, in part, could have applied likewise to typhus and even to less severe maladies like the graver types of influenza, although the latter has greater individuality than other pandemics. The term coqueluche came to mean an acute epidemic bronchitis and eventually whooping cough.

THE PROBLEM OF THE DECLINING BIRTH RATE.

A DECLINING birth rate seems to be a penalty or outcome of civilization. By some it is regarded as disastrous and as a prominent symptom of a nation's decay. By others it is looked upon as beneficial and of good augury when the decrease in births affects all classes of society alike. There is weight in the arguments brought forward by both sides and, in any event, it is wisest to look the matter in the face, as in civilized countries a declining birth rate has come to stay, and the more cultured the country the fewer the children. The movement began in France, Great Britain followed suit, and in Germany its course before the war was remarkably rapid; in fact, all Europe with the exception of Russia and the Balkan States, which chance to be the least advanced in civilization, has taken part in the movement. This country, more especially its native born population, and the British self-governing dominions are affected to the same extent as Europe. There is little doubt that in time Japan, China, and the East will fall into line when the movement will be absolutely world-wide. Now as to the causes of the declining birth rate: According to Dr. C. Killick Millard, writing in the *British Journal of State Medicine* for November, 1918, the fall in the birth rate is due chiefly, if not entirely, to the volitional restriction of the size of the family, that is to the adoption of birth control measures. This is, however, going too far, and it would be more discreet to say that birth control methods are partly responsible for decreased birth rate. It is obvious that social status has a very marked effect upon the birth rate. The best educated and most prosperous class have fewest children and the lowest infant mortality while the unskilled workmen average about twice as many children among whom the mortality is about twice as high. On the whole, though, while the high mortality among the children born where the birth rate is high largely reduces what may be termed the effective birth rate, the number of children surviving among the lower social groups still exceeds the number surviving in the higher groups, with the result that the lower strata are adding most to the population. This is the disquieting phase of the situation from the standpoint of eugenics, and is more disquieting, perhaps, in this country than in Europe, for the reason that the foreign born population, which is mainly obtained now from the most uncivilized parts of Europe, is increasing at a much

greater rate than the native born population of all grades of society. The members of the better instructed classes and the professions are among those who have the smallest, while the ignorant have the largest families. This appears to be a feature of dangerous import and one which should be looked into, considered in all its bearings and dealt with in the most fitting way. Overmaternity is bad for all concerned; for the women, because it wears them out and makes them old before their time; for the children, as they are ill nourished and do not develop physically or mentally as they should; and for the country and the race, as inhabitants which are not able to contribute their quota of brain or physical work constitute a detriment rather than an asset to a land. It may be allowed that quality is better than quantity and this statement applies to human stock. On the other hand, it would appear that if the educated classes, which naturally include the skilled artisans and laborers, do not have larger families they will be swamped by the unskilled and ignorant workers. The problem is one which calls for serious study.

SIDELIGHTS ON PEDAGOGY.

THE recently published report of some experiments from the psychological laboratory of Vassar College* furnishes data for speculation as to the intrinsic value of present-day pedagogy. It also throws light on the relation between literary and mathematical gifts. The tests were made on members of the Freshman class, who, it may be presumed, had come to college fresh from the intensive culture of the most approved preparatory schools.

The inquiry into the correlation between a taste for mathematics and for writing revealed that a student who reports that she dislikes to write is much more likely to say that she is interested in mathematics than is one who reports that she likes to write. A student who claims accurate verbal memory is likely to be fluent in oral recitation. More significant, however, is the finding that both the verbal memory tests and the "reading backwards" test are better indices of academic success than the "hard direction" tests. In other words, the *sine qua non* of getting along at school is a good memory. The ability to repeat by rote the substance of a lecture delivered by a poorly paid teacher who has gotten it from a text-book, written in turn probably by another poorly-paid teacher, will be followed by academic success, while the capability of original thinking, if accompanied by a poor memory, will meet with poor marks and failure.

The relationship between tastes for letters and for figures discovered by the psychologist harmonizes with the views of the laity who are inclined to think that a strong leaning towards either one of these branches necessarily precludes aptitude for the other. The general attitude is that literary proclivities are to be rated more highly than quickness at figures; there are three reasons for this. One is the existence of mathematical prodigies who are otherwise mentally deficient; the second is the somewhat contemptuous way in which Oliver Wendell Holmes speaks of mathematics, and the third is the fact that literary men form largely public opinion and naturally disseminate the idea that literary taste is the most desirable of all and literary men the most to be envied of all classes.

*"Minor Studies from the Psychological Laboratory of Vassar College. XXXIV. A Further Study of Freshmen." By M. Montague, M. Reynolds, and M. F. Washburn. *American Journal of Psychology*, July, 1918, pp. 327-330.

THE PROTECTIVE MASK IN CONTAGIOUS PLAGUES.

DOCTOR PLICQUE writes on this subject in the *Journal de médecine et de chirurgie pratiques* for October 25. The use of these masks goes back to great antiquity, and apparently was very extensive. Excessive fetor of the breath was regarded to a certain extent as indicative of contagion. In the plague of Athens, in 429 B. C., the fetor, which was cadaveric in type, was said to have been perceptible at a great distance. In the great pestilences of the Middle Ages, the custom of wearing a cloth before the face, saturated with some real or supposed antiseptic, is frequently mentioned by contemporaries. The modern, systematic use of a mask for lung plagues goes back only to recent years. It was originally suggested or devised by Broquet, according to the writer, who, however, gives no data as to time, place, etc. We are told that this mask was used in the severe epidemic of the Manchurian pneumonic plague which prevailed in 1910-11. The Japanese surgeons also devised a mask for this emergency, while others were extemporized. It is worthy of note that certain members of the profession ridiculed the idea of the mask (just as was the case in the recent epidemic of influenza); and they paid the penalty by contracting and dying from the disease. The conditions are by no means the same, for the deadly type of grippe-pneumonia was not transmitted as such, but as the basic influenza, and we were informed that but 3 per cent. of these grippe-pneumonias were primary, so far as New York was concerned. In the Manchurian plague, French and Russian physicians perished until they began to use the masks, while the Japanese, who wore them from the start, did not lose a man among physicians or medical auxiliaries. According to Plicque, the grippal bronchopneumonia may be very contagious, especially in the adolescent and younger men, and when these are poorly nourished the fulminant course is appalling. While patients cannot, of course, wear masks when actually ill, they should make use of them during the period of recovery to prevent their entourage. The author is inclined to regard, like the ancients, unusual fetor of breath as evidence of contagiousness.

SANITATION AND MEDICAL GEOGRAPHY IN PORTO RICO.

DURING the past year, Dr. Gonzalez Martínez delivered an address before the Porto Rico Senate on the above subject, which has been published in both Spanish and English, in the form of a Senate docu-

ment. The medical geography of the island, he says, is yet to be written. The chief causes of morbidity and death are still tuberculosis, malaria, and hookworm disease. The death rate from typhoid shows some improvement, but this is offset by a marked increase of dysentery. Neither of these maladies has a high incidence, however. Smallpox, not long ago believed extinct, has recently reawakened. All in all, sanitation has made little advance in endemic epidemiology. If we turn to infant mortality, conditions are much worse, for more children are dying than was the case seven or eight years ago. The new sanitary organization has been in operation now for six years past, and the death rate has remained constant at about 22 per 1000. This is, of course, far lower than in former decades, but it ought to show a further decline. What is the factor that is nullifying the efforts of the new sanitary organization? There is, as yet, no geographical census of malaria, dysentery, and certain maladies due to sensible parasites (not including hookworm). The mosquitos and other disease-transmitting insects have not been studied geographically. This omission goes back to the charge of deficient appropriations in 1912 and subsequently. After the conquest in 1898 the U. S. Government stamped out smallpox, and the island was protected from yellow fever. At a later period the discovery of the hookworm on the island led to a powerful campaign against it. These advances have been maintained by the insular authorities. But the island cannot be termed salubrious as long as malaria is so prevalent (nearly 2000 deaths a year in 1916-17). A survey of this affection on a small scale in 1914 gave results which showed its great prevalence in one locality, but despite this object lesson the crusade was not expanded. Even in this particular nest of malaria nothing has ever been done to relieve it. A medical survey of the island could be taken over in part by the agricultural and meteorological services. Different localities harbor different diseases in latent form. To search out and eradicate these foci requires, first of all, a suitable geographical census.

Physiology of Swimming.

This subject has recently been studied at first hand by Liljestrand and Stenstrom, who reported their results in the *Svenska Läkaresällskapets Handlingar* for September 30. There were 9 experiment subjects whose respiratory exchange was measured under varying conditions. Two of the men, who weighed 90 kilos (198 pounds) each, and were well developed muscularly, and also plump, were contrasted with a man who weighed but 51 kilos (112 pounds), and was thin and slender. The breast stroke was used, and over short distances only. The speed was about 50 meters a minute. The stout men, under the effort, developed rapid breathing and increased gas exchange. The respiratory quotient increased until it almost equaled 1.00. The oxygen consumption increased from about 800 c.c., to 2,800 c.c. The thin control under the same conditions showed a respiratory quotient which at times far exceeded 1.00, but the consumption of oxygen did not go beyond 2,000 c.c. per minute. For low and medium velocities the absolute consumption of oxygen was greater in the light man than in his adversaries. The consumption per 1,000 per stroke, with regard to speed, was estimated at 42 c.c., equal to 206 calories. These experiments were varied in numerous directions with especial reference to speed, resistance of the body, blood pressure, respiratory exchange, etc. It appears certain that the work of inspiration in water is increased, perhaps by 50 per cent., in comparison with efforts on dry land. The experiments on resistance in water were carried out in part by towing the subjects, and appeared to show that there was a notable coefficient in this respect, depending on the individual constitution. To a certain extent the resistance increased with the rapidity of towing.

Recrudescence of Rabies as a Result of the War.

Among the plagues to follow the great war rabies must be reckoned with. Already it has reappeared in England, while from the very beginning an increase was apparent in France. Before the struggle began, Belgium and the districts doomed to be occupied in Northern France swarmed with dogs and rabies was sufficiently common. This abundance was due in part to the extensive use of the dog as a draught animal in those localities. After the invasion these animals moved westward in large numbers. They appeared to breed as usual and were under little or no police supervision, although conditions for suppressing the danger were most favorable. Rabies showed an increase from the North Sea to Switzerland, and was carried far into the interior of France. Here police protection was as good as absent. The type too is virulent as shown by the short incubation period. Lenoir, who writes to the above effect in a health bulletin abstracted in the *Journal de médecine et de chirurgie pratiques*, was the officer in charge of an antirabies campaign in South Africa in 1902, and describes the manner in which the disease was suppressed at that juncture. After his arrival a preliminary investigation showed that rabies was really present. Orders were at once issued to dog owners to destroy or intern all dogs presenting symptoms suggestive of rabies. All other dogs were ordered chained up or muzzled. All unmuzzled dogs were ordered killed. Heavy penalties for noncompliance with the law were enforced. During the ensuing four months 80,000 dogs were destroyed. Thousands of muzzles were supplied by the Government at six francs each. As a result the disease was utterly stamped out, as has also been the case in Tunis and Canada. All three of these missions were conducted by the Paris Pasteur Institute.

News of the Week.

Influenza Reviving.—A warning was issued to the country, on December 11, by Surgeon General Blue of the Public Health Service that the influenza epidemic was by no means ended. Reports received by the service show a recrudescence of the disease in practically every part of the country. Surgeon General Blue advises the closing of schools on the first sign of the reappearance of the epidemic and observes that the disease

now tends to occur more frequently among school children. Conditions are said to be worst in Pennsylvania, Louisiana and on the Pacific Coast. In Boston and nearby cities there has been a recrudescence of the disease, 7002 new cases having been reported to the Massachusetts State Department of Health within a week; most of the cases in this locality are said to be mild in character. The conditions in Wheeling, W. Va., are as bad as at the height of the epidemic. There has been a sudden increase in the number of influenza cases in Cleveland. Baldwin-Wallace College at Berea and the Ohio State Normal School at Kent have been closed under quarantine. In New York City the number of cases reported daily is about the same as during the past three or four weeks, there being sometimes an increase and again a decrease in the number of new cases reported, the number running between 100 and 200 a day, which is but little above the average for this time of the year. Dr. Copeland warns that sporadic outbreaks of the disease are to be expected during the winter and that precautions against the spread of the disease, especially as regards coughing and sneezing, should not be relaxed.

A Drug Epidemic in London.—A special cable despatch from London to the New York *Sun* states that a drug epidemic of the worst nature has broken out in London within the past few weeks. The existence of an organization which might be termed a vice trust has been unearthed. It is said that women as well as men are victims of the drug craze and many soldiers have succumbed to the cocaine habit. The explanation of the serious and widespread nature of this epidemic of drug addiction is that the nervous tension produced by the stress and strain of war has sapped the vitality of the people and they have turned to drugs, sedatives, and stimulants largely because war conditions have closed other channels of distraction.

Rockefeller Foundatin Renews Fight on Disease.—Dr. George E. Vincent, President of the Rockefeller Foundation, which has an endowment of $100,000,000, announces that the organization, after diverting its activities for four years to war relief and army welfare work, in which it expended $21,000,000, will resume its work of attacking disease in every part of the world. The peace program contemplates the expenditure of millions of dollars. A campaign will be launched to wipe out the plague in China and other countries of Asia. The medical university in Peking, China, being erected by the Foundation at a cost of $6,000,000, will be opened not later than October, 1920. Another medical university will be built at Shanghai, China. Maj.-Gen. William C. Gorgas will soon head an expedition of scientists to Central and South America, where a campaign against yellow fever will be launched.

Anthrax at Bellevue Hospital.—Bellevue Hospital has recently had its fourteenth operation for anthrax, when a man was operated upon on December 13. The infection occurred through a slight cut on the cheek which the victim received while being shaved two days previously.

Bureau of Venereal Diseases.—The following permanent appointments to the staff of the Bureau of Venereal Diseases of the New York State Department of Health have been made: Chief, Dr. Joseph S. Lawrence; Consultant, Dr. Howard H. Marsh; Hospital and Dispensary Inspector and Organizer, Dr. Walter S. Goodale; Lecturer on Social Diseases, Dr. F. S. Honsinger; Supervising Nurse and Social Worker, Maud Casey.

Request for Medical Research Work.—Under the will of Captain Raphael De Lamar, his residuary estate, estimated at $10,000,000, is to be equally divided between the Harvard University Medical School, Johns Hopkins University, and the College of Physicians and Surgeons of Columbia University. The income of these funds is to be used for the study and teaching of the origin of human disease and the prevention thereof; for the study and teaching of dietetics, and of the effect of different foods and diets on the human system; and in connection with the foregoing purposes to establish and maintain fellowships, instructorships, scholarships; to construct, maintain and equip laboratories, clinics, and dispensaries, and other places for such study and research, and to provide for the publication and dissemination of the results of such study, not only in scientific journals and for physicians but also by popular education, public lectures, and other appropriate methods for reaching the people generally. The will requests that the fund be kept intact.

Work of Influenza Commission.—The commission for the study of the cause, prevention, and treatment of epidemic influenza appointed by Governor Whitman on October 21, of which Dr. Hermann M. Biggs is the chairman, announces that the first work which is being undertaken is the attempt to reach a definite conclusion as to the value of influenza vaccines in preventing the disease. A large number of different groups of people in institutions, cantonments, factories, hospitals, prisons, and the practice of various physicians, will be studied so that it is hoped that before long a definite statement may be made on this subject. Surveys of certain cities, not only in New York but in other States, will be made in order to study the cause of the local epidemic, the probable point of entry, the method of spread, types of the disease, the effect of age, sex and nationality, and the incidence, morbidity, and mortality rates. It is probable that in the States that have not been invaded, especially in the West, special studies will be made in regard to prevention by vaccines and the value of quarantine.

Cost of Medical Education.—In commenting on the gift of $10,000,000 bequeathed to the Harvard Medical School, the College of Physicians and Surgeons of Columbia University and Johns Hopkins by the late Captain Joseph Raphael De Lamar, Dr. Samuel W. Lambert, Dean of the College of Physicians and Surgeons, tells what this gift means to the institution with which he is connected in carrying it nearer the goal it has set for medical education in New York. Regarding the financial status of our large universities, he says there is no danger of their having more funds than they need. Neither Columbia University nor any other which he knows is operated at a profit. The school of medicine is one of the

most costly departments at Columbia University. It costs the University $3,000 to educate a man for the degree of M.D., yet of this sum the student pays only $1000. During the past five years the teaching staff of the medical school has contributed between $25,000 and $30,000 to the school for one purpose or another.

Bequests to Hospitals.—Under the provisions of the will of Edward Oppenheimer, Mount Sinai Hospital, New York, receives a bequest of $10,000, the Hebrew Benevolent and Orphans' Asylum and the Montefiore Home each receive $1,000, and the Lenox Hill Hospital $500.

Hospital for Diagnosis.—About two years ago an association called the New York Diagnostic Society was chartered by the State, the announcement of its organization being made at a dinner given to Dr. M. Joseph Mandelbaum, the founder. The society, which now has a membership of about 400, under the presidency of Dr. Mandelbaum, is about to erect a hospital on West Seventy-second Street, in this city, to be devoted exclusively to diagnosis. The institution, which is not really a hospital, will be known as the West Side Branch of the Diagnostic Clinics of the Academy of Diagnosis. The building will be six stories and basement, with Indiana limestone front, and will be provided with the most modern equipment required for diagnostic investigation and tests. The officers of the society are Dr. M. Joseph Mandelbaum, *President;* Dr. Monroe Bradford Kunstler, *Vice-President;* Dr. Lesser B. Groeschel, *Secretary;* Dr. J. Maxwell Van Dyk, *Treasurer.*

Committee to Study Influenza.—As the result of a long discussion in which opinion was about equally divided as to the value of certain practical measures for the prevention of the spread of influenza, the American Public Health Association, at its closing session, in Chicago, on December 13, appointed a committee of five to consider the question whether influenza masks and the closing of churches and places of amusement are of practical value in the spread of influenza.

Dr. A. E. Stanley, who has been first assistant superintendent of the State Hospital for the Insane at Waterbury, Vt., has been appointed superintendent of the State Board of Control, to succeed Dr. W. L. Wasson.

Dr. J. E. Vanderpool has resignated his position as city health officer of the city of Walla Walla, Washington.

Medical Society Elections.—The American Association for the Study and Prevention of Infant Mortality, at its ninth annual meeting, held in Chicago, December 5 to 7, 1918, elected the following officers for the ensuing year: *President,* Dr. S. Josephine Baker, New York; *President-Elect,* Dr. Phillip Van Ingen, New York; *First Vice-President,* Dr. William Palmer Lucas, San Francisco; *Second Vice-President,* Dr. W. S. Rankin, Raleigh, N. C.; *Secretary,* Dr. Henry F. Helmholz, Evanston, Ill.; *Treasurer,* Mr. Austin McLanahan, Baltimore; *Executive Secretary,* Miss Gertrude B. Knipp, Baltimore. There were 17 States represented, also the District of Columbia and Canada.

The Seaboard Medical Association, at its annual meeting, held in Kingston, N. C., December 5, 1918, elected the following officers for the ensuing year: *President,* Dr. W. L. Harris, Norfolk, Va.; *Vice-Presidents,* Drs. C. B. McNairy, Kingston, F. M. Burfort, Fentress, Va., J. H. Mitchell, Ahoskie, Va., and J. G. Goode, Cheriton, Va.; *Treasurer,* Dr. George A. Caton, New Bern, N. C.; *Secretary,* Dr. Clarence P. Jones, Newport News, Va.

The "Southern Practitioner" of Nashville, long so ably edited by Dr. Deering J. Roberts, has ceased publication with the December issue, and will be incorporated with the *Medical Review of Reviews* of New York.

The "American Journal of Orthopedic Surgery," which is the official organ of the American Orthopedic Association, announces that with the coming year it will enlarge its scope by serving also as the official organ of the newly formed British Orthopedic Association. Henceforth the name of the publication will be *The Journal of Orthopedic Surgery.* It has been felt by the two associations, which count among their members both the Director General of Military Orthopedics for the United States, Colonel Brackett, and the Inspector of Military Orthopedics for the British Empire, Maj.-Gen. Sir Robert Jones, that the best interests of the great mass of mankind now suffering from crippling disabilities will be furthered by such an amalgamation. The journal will be published as heretofore by Ernest Gregory of Boston. The committee appointed by the British Orthopedic Association consists of R. C. Elmslie M. S., F. R. C. S., T. R. Armour, F. R. C. S., W. H. Trethowan, F. R C. S., and H. Platt, M. S., F. R. C S. Dr. R. W. Lovett and Dr. C. F. Painter comprise the committee appointed by the American Orthopedic Association.

Influenza in Porto Rico.—It is estimated that there are 100,000 cases of influenza in the Island of Porto Rico. Governor Yager of Porto Rico, in compliance with a request from Dr. Ruiz Soler, the Commissioner of Health, has ordered all schools, churches and theaters closed and has put a ban on public gatherings. The Labor Federation has requested aid and has asked that the United States Public Health Service be placed in charge of the situation. Secretary Baker has advised Governor Yager that the Public Health Service would co-operate with the insular authorities.

The New York State Nurses Association, at its seventeenth annual meeting, held last week in Rochester, adopted resolutions favoring the Lewis Baker bill, now before Congress, which provides for military rank for nurses who serve in the country's war forces, and favors an eight-hour day for nurses and apprentices in hospitals. Miss Elizabeth Golding of New York was elected president, and Brooklyn selected for the eighteenth annual meeting of the association in October, 1919.

Deaths Due to Motor Vehicles Increase.—The National Highways Protective Society's report shows that during the month of November 131 persons were killed by automobiles in New York State as compared with 81 a year ago. In New York City, automobiles killed 64, trolleys 5, and wagons 3. In New Jersey they were 19 deaths by automobiles, two by trolleys, and two by wagons. Eight persons were killed at grade crossings in each State.

The Late Dr. Bissell.—The executive committee of the Medical Board of Bellevue Hospital records with profound sorrow the death of their esteemed colleague, Dr. Joseph Bidleman Bissell, major, Medical Corps, U. S. Army, chief of the surgical service at Fort McHenry, Md., and visiting surgeon and surgical director of the Fourth Division of Bellevue Hospital. His self-sacrificing devotion and unflagging energy were always given to the sick poor of this hospital. In his death Bellevue Hospital has lost a skillful surgeon, the community has lost a useful and patriotic citizen, and his colleagues have lost an amiable and lovable personality. At a time of life when most men of his age might reasonably expect that the defense of our nation's right might safely be left to younger men he volunteered for active duty in the service of his country. He died in that service as a result of the strenuous life incident to camp duty, and his death is no less glorious than if it had occurred in the face of the enemy and on the field of battle. George D. Stewart, M.D., *President;* Charles E. Nammack, M.D., *Secretary,* Executive Committee, Medical Board, Bellevue Hospital.

Obituary Notes.—Dr. Guy Halifax Wallace, a graduate of the University of Toronto Faculty of Medicine in 1909, died suddenly at his home in New York City on December 9, aged 32 years.

Dr. James Smith Ford died November 21 at the Loomis Sanatorium, Loomis, New York, where he was first assistant physician, aged thirty-three years. He was a graduate of the College of Physicians and Surgeons, Columbia University, in 1910; a member of the Medical Society of the State of New York, the National Tuberculosis Association, and the American Sanatorium Association, and was an associate editor of the *Journal of the Outdoor Life,* secretary to the Sullivan County Committee of the Medical Section of the Council of National Defense, local draft examiner, and examiner in tuberculosis for the War Risk Insurance Bureau.

Dr. David Cole Carr, a graduate of Bellevue Hospital Medical College in 1868, died at his home in New York City on December 7.

Dr. Charles Henry Shelton of Montclair, N. J., a graduate of the New York Homeopathic Medical College and Hospital in 1880, died at Lajolla, Cal., on December 11, aged 64 years.

Dr. Henry Gustav Beyer, Medical Director, U. S. N., retired, a graduate of Bellevue Hospital Medical College in 1876, died at his home in Washington on December 9, aged 68 years.

Dr. William Turner Parsons, a graduate of Johns Hopkins University in 1910, died of pneumonia at his home in Palmer, Mass., on December 9, aged 37 years. He was formerly instructor in pathology in Johns Hopkins University, and also connected with the Baltimore Eye, Ear, Nose and Throat Infirmary. He was a member of the American College of Surgeons and of the American Medical Association.

Dr. Joseph A. Marvin of Holyoke, Mass., died of pneumonia on December 7, aged 57 years. He was a graduate of Laval University Medical Department, Montreal, Can., in 1889, and a member of the Holyoke Board of Health. Dr. Marvin served as city physician in 1902 and alderman-at-large in 1899 and 1900.

Correspondence.

THE ABORTIVE TREATMENT OF INFLUENZA WITH QUININE DIHYDROCHLORIDE.

To the Editor of the Medical Record:

Sir:—The remarkable abortive results observed by us in the treatment of influenza through the intravenous injection of quinine dihydrochloride, leads us to believe, although the cases thus far treated are too few to permit of scientific certainty, that, properly used, the intravenous injection will prevent or astoundingly diminish the number of later progressive pneumonias and the corresponding high mortality. Without delaying further for the purpose of corroborating our results, we wish to submit the technic we have found effective.

Influenza, starting with a sudden onset, headache, backache, prostration, loss of appetite, chilly sensations, rise in temperature, pulse, and respiratory rate, is from the outset a lung infection with a patch of pneumonic consolidation and systemic toxemia. However, for a period of hours or for three to five days the process in the lung remains more or less localized, and physical signs in the chest may be lacking. The temperature ranges from 100.5° to 103°, but is irregular; the pulse rate is usually comparatively slow, about 90 or under 100 with the patient in bed, more rapid and with low pressure if ambulatory, while the respirations are increased to only about 26 per minute. The most marked subjective symptom, apart from headache, backache, or prostration, is the hacking, spasmodic cough, frequently leading later in the disease to rupture of lung tissue at the consolidated area or at the site of an old tuberculous infection, followed by pneumothorax and empyema. The urine examination shows increased acidity, and early a trace of albumin occurs which becomes a heavy cloud in progressively severe cases.

The disease may be controlled naturally and convalescence established upon the second, third, fourth, or fifth days. On the other hand, a rapid transgression into a probable septicemia may occur, and a fatal progressive massive pneumonia may involve one or both lungs. The cough increases, the temperature remains more constantly high, the pulse rate goes to 120, and the respirations to 36 or more. Mentality, however, remains remarkably clear in most cases. In the usual case of influenza, however, the course of the disease is slower, covering a period of seven to fourteen days before the fatal outcome, and the more insidious progression arouses false hopes. It is particularly in this, the usual type, that the time of election for the use of quinine dihydrochloride is lost, for although quinine has long been used in the treatment of pneumonia, in influenza we are convinced that it should be used before resistance is lowered and pneumonia is extensive. Nature is permitted to develop immunity, if possible, but when it is evidenced that spontaneous recovery is becoming doubtful the intravenous injection of quinine is given at once.

The positive indications for the intravenous quinine treatment are as follows: (1) When the disease shows no retrogression in three to five days.

(2) When the temperature climbs and remains more constantly high. (3) When the pulse, previously slow, crosses 100. (4) When the cough increases. (5) When rusty sputum or physical signs of definite pneumonic consolidation occur.

Quinine dihydrochloride is used in 3 to 10 per cent. solution. In the young, where a vein is not easily obtainable, it is used intramuscularly in a dosage of 1½ grains to each year of age. We have used 7½ grains in a very sick child, age 4, who had run a constant temperature of 104° to 105° for two days, with increasing cough, but no extensive lung consolidation, with the result that the temperature was 100.5° twelve hours later, and reached normal the following day with complete recovery. Intravenously, 7 to 20 grains are used. An intravenous injection of 22½ grains was given a private patient at the Park Hospital. He had a temperature of 104° at the time of injection, a pulse of 90 to 105, respirations 26, headache, severe pain at the pit of the stomach and in the back, and had been ill for five days with no evidence of a possible spontaneous recovery. The intravenous injection was followed by a temperature drop in 2 hours to 101.5°, resembling that in the crisis of lobar pneumonia. Twelve hours later it was 100.5°, and did not rise again above 100° and a fraction. The appetite returned, pulse and respiratory rates fell, all distress disappeared, and his only complaint was that he had been permitted to suffer five days. The irritative cough in these cases remains, gradually diminishing, for several days.

The quinine solution is injected slowly and warm during a period of from ten to twenty minutes. The sensations produced are those of relief from pain, tingling and warmth, at first a slight dilatation of the pupil, some dizziness, interference with hearing, slight mental aberration in some, and occasionally vomiting during the injection.

17 EAST THIRTY-EIGHTH STREET.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE MEDICAL PARLIAMENTARY COMMITTEE—REPORT ON SCURVY—INFLUENZA EPIDEMIC—DEMOBILIZATION OF THE MEDICAL OFFICERS OF THE ARMY.

LONDON, November 23, 1918.

AT a recent meeting in London, under the presidency of Sir Henry Morris, of medical men interested in obtaining for medicine more adequate representation in Parliament, a committee was formed to forward the necessary work. The committee, which has now definitely styled itself the Medical Parliamentary Committee, has developed its initial energies in two directions: (1) the preparation of a list of medical men willing to stand for Parliament; and (2) the institution of a sort of Medical Advisory Board to be at the disposal of medical men in Parliament who might require to be placed in possession of the accepted medical view upon new bills or current topics. For medical men who are able to leave their practices and enter Parliament must soon get out of touch with general professional life, however adept they may remain in special directions—it is doubtful whether the great Clemenceau remembers that he was once a general practitioner in the north of Paris, while Sir Auckland Geddes and Dr. A. Addison, in our Parliament, would be quick to repudiate clinical skill, even while they can claim to retain familiarity with the ancillary sciences. All these statesmen would require instruction to make them see fully the way in which a Parliamentary Bill might affect the professional life of medical men, prejudice the quality and conditions of their service, and so lead to mal-administration of sanitary machinery. The institution of a Medical Parliamentary Committee, which could take on consultative duty with regard to new legislation, is therefore a valuable move for the public and for the medical profession; but the committee can only succeed if it is supported in an important and representative manner by the medical profession as a whole. It is necessary that its advice upon doubtful professional points should be given with the authority of a common voice, and it is exactly here that some risk appears. At the original meeting, at which the Medical Parliamentary Committee came into being, the British Medical Association made a composite appearance. The president of the association blessed the movement; the late chairman of the most important of the central committees of the association contributed a forceful supporting speech to the debate, while a prominent official of the association followed in a speech denouncing the object of the meeting or the circumstances in which the meeting was being held. The representatives of the association were chosen upon this committee, believing the association to be in accord, but later they resigned upon the direction of the council of the association. The British Medical Association appointed this August a Parliamentary Election Committee with much the same objects, from the viewpoint of the association, as those which are held by the Medical Parliamentary Committee on general grounds. If the two bodies cannot work together neither will be of the slightest use as an authoritative voice to the public upon doubtful points.

Comments have already been made in these columns upon the valuable manner in which the highest scientific authorities available in the country have placed their expert knowledge at the disposal of the Government for such elucidation of broad and particular problems as might have general bearing on national health, including alike the health of Navy, Army, and the civilian population. In view of the fact that outbreaks of scurvy have occurred with the armies at various times both in Great Britain and abroad, the Food (War) Committee of the Royal Society decided to conduct an investigation with the object of making some definite pronouncement as to the cause, and therefore as to the logical prevention, of the disease. Some of the outbreaks during the war have been serious, and it is evident that they may recur. For the process of demobilization will be a long one and for an extended period of time vast British forces will have to be retained abroad, and sometimes at places far removed from sources of good food supply. The pronouncement of the committee, which has now been published, was based chiefly upon investigations which have been carried out at the

Lister Institute by Miss Harriette Chick, D.Sc., and the statement as to the cause has nothing new about it save the definite recognition of the presence in many foods of an accessory substance, "vitamine," whose nature remains unrecognized, but whose influence is indubitable and whose literature is now bewilderingly extensive. Scurvy, like beriberi, is due to the long-continued consumption of food lacking in vitamines—this conclusion of the Royal Society Committee was a foregone one. These substances, contained in a number of fresh foods, are a special characteristic of oranges, lemons, and fresh green vegetables, though turnips, potatoes, and other roots and tubers contain them, while they are found more sparsely in fresh meat and milk. Vitamines are deficient, or wholly wanting, in all dried or preserved foods, and are also destroyed by prolonged heating—a practical example of this phenomenon being that potatoes in stews possess no vitamines, while rapidly boiled potatoes still contain traces. Two other general points are that there is no association between scurvy and tainted food, and that, as alkalies destroy antiscorbutic properties, soda should not be added to the water used for the cooking of vegetables. One quite new thing in the Royal Society's Report has relation to "lime-juice," which is found quite useless for prevention in case of scurvy. This is very significant because the popular view, and one endorsed until lately by the medical profession, has been that in West Indian lime-juice we possess a specific against scurvy. Fresh limes have a faint antiscorbutic action—say one-quarter that of lemons—but lime-juice as popularly employed has no efficiency. At once an appeal will be made to history, and where contradiction might be expected confirmation will be found. The so-called "lime-juice," by the regular administration of which scurvy was eliminated from the British Navy during the first half of the nineteenth century, was lemon juice. Nares's famous Arctic Expedition of 1875 was embarrassed and well-nigh ruined by serious outbreaks of scurvy, and this expedition was the first to be provisioned by "lime-juice" which was lime-juice, and was prepared from West Indian limes and not from Mediterranean lemons. Further information in the statement of the Royal Society Committee is the fact that while potatoes and root vegetables are far less effective as antiscorbutics than oranges or lemons—the juices of which are equal in value—still a daily ration of three-quarters of a pound of rapidly boiled, *not stewed*, potatoes will prevent scurvy. Beans, peas, and lentils in the dried condition have no antiscorbutic properties, but if the dried seeds, having been soaked in water are allowed to germinate for 48 hours, they develop an antiscorbutic vitamine, and are at the same time valuable foods from other points of view. The method adopted for germination is as follows:

The beans, peas, or lentils are soaked in water at room temperature for 24 hours. The water is then drained away, and to permit germination the soaked seeds are spread out in layers not exceeding two or three inches in depth, and kept moist for a period of about 48 hours at ordinary room temperature (60 deg. Fahr.). They should not be allowed to dry after this operation, but should be cooked as rapidly as possible. It emerges from this advice that lime-juice should be replaced by lemon juice in the diet of all communities liable to scurvy; that germinated beans, peas, or lentils should form part of the regular daily ration in such communities, and that vegetable foods should be cooked for as short a time as possible at boiling point.

The last week of November is seeing, if figures may be trusted, the real abatement of the influenza epidemic. The Registrar General's reports for the preceding week were serious, but in the 96 great towns of England and Wales (including London) just short of 6000 deaths occurred as against 7500 in the second week of the month. The Local Government Board have made regulations to take effect in all places of public amusement, especially in respect of ventilation. No entertainment may last more than three consecutive hours, and if a second performance follows the building must be thoroughly ventilated for at least half an hour. No doubt, this procedure will be helpful, but those who point either to the efficacy of ventilation or the activity of the Local Government Board, when referring to the abatement of influenza, should remember that the mitigation of the evil started well before the measure of remedy.

As the British share in the enormous army of occupation holding German soil and key positions during the arrangement and discharge of peace terms will necessarily be considerable, it is clear that a certain proportion of the 12,000, or more, civilian doctors who are holding territorial or temporary rank in the Royal Army Medical Corps must still remain for some time away from their practices. But in what order should they return? Justice would say that those who had been in the service longest should return first, but such justice would be very rough, for all the conditions of medical service are not identical. Many of the territorial officers have been able to remain in touch with their practices, so that not only have their pecuniary interests been to some extent safeguarded by the retention of some of their civil practice, but their term of military employment has not been attended with any risk to life or limb. Some of these men have done full four and a quarter years' military work, but it is widely felt that other officers, temporary officers, who have served but two years, can put in better claims for preferential treatment. Those two years may have taken them far afield, and subjected them to all the risks of plague, pestilence, and famine, as well as the dangers of the fighting front. The price they have paid is shown by the apalling number (proportionally speaking) of deaths that have occurred in their *cadre*. These deaths have been registered among a class which includes most of those who have for varying and sometimes long periods been absent from their practises, and every medical man knows that if he severs all connections with his clientèle for an extended time he runs a great risk of having to begin again building up a connection. Clearly, the principle of demobilization upon the consideration of length of service only is but a partially just one, and may be in some instances a markedly unjust one. A writer to the *Lancet* suggests that the temporary medical officers required by the army should now be taken from those who have hitherto

not served, owing to their civilian work being "indispensable to the country." Does he speak humorously or bitterly? The suggestion, of course, is that these men were not indispensable—otherwise they would be wanted as much as ever—but that they did not want to go while there was fighting. This, in many or most cases, is an unfair inuendo. Many men were willing and anxious to go whose public or private affairs retained them at home. The whole matter of demobilization of medical men with the Army requires delicate handling.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

GRIPPE IN PARIS CAUSES INCREASED DEATH RATE—NATIONAL TESTIMONIAL AT SORBONNE TO AMERICAN RED CROSS—DANGER OF BATTLEFIELD SOUVENIRS—MISS JULIA STIMSON MADE HEAD NURSE OF ARMY.

PARIS, November 18, 1918.

THE grippe epidemic continues in France, and in allied, enemy, and neutral countries. At this time of the year the usual death rate in Paris is 721. Last week 1,944 were reported, and of this number, 880 were attributed to grippe and 202 to bronchial pneumonia. The steps taken in Paris to combat the disease seem to consist of increasing the number of doctors, ambulances, and beds to take care of victims. The French military authorities have placed seventeen doctors at the disposal of the municipality, and the American Red Cross has placed nine ambulances at the disposal of the city. Certain trains have been taken off the railroads in France because of the number of employees who are ill with the disease.

There is very little new to be said on the treatment of influenza. Many people who escape attribute their immunity to quinine or the ammoniated tincture; others pin their faith on cinnamon; and a very large number believe in inhaling eucalyptus oil. All these are often preventive as well as curative. The first great point is to avoid the occasion of infection. No one who can help it should go into crowds where people are coughing and sneezing. We know now that this is the way in which influenza is conveyed. Traveling in trains, tramway cars, and omnibuses should be avoided as much as possible. There is nothing like plenty of fresh air for warding off influenza. Railway carriage windows should be kept open and bedrooms well ventilated. People who are really well at the time are not likely to catch influenza. It is not easy to satisfy this condition, but the utmost care should be taken not to lower the resisting power by getting chilled, wet, or fatigued. No one should go long enough without a meal to make him feel faint. Plenty of sleep is a wonderful preservative from all infections, and it is, therefore, prudent to go to bed early. Pneumonia has always been a dangerous accompaniment of influenza, but it is more than usually common in the present epidemic. For this reason, even a mild attack of influenza should be taken seriously.

The American Red Cross received the homage of representative Frenchmen yesterday at a ceremony organized at the Sorbonne by the Comité Effort de la France et de ses Alliés. The meeting was presided by M. Louis Barthou, former Prime Minister, and the speakers included M. Mourier, Under Secretary of State for the Sanitary Service; M. Firmin Roz, Mme. Jules Siegfried, Admiral Touchard, General Malleterre and Mr. Henry P. Davison, president of the War Committee of the American Red Cross in Washington. The ceremony was attended by members of the Diplomatic Corps and of the French Government, and opened with the "Marseillaise," played by the band of the Garde Republicaine. Mme. Abby Richardson of the Opera Comique, sang the "Star Spangled Banner" and "Dixie" and M. Roger Gaillard, of the Comedie Française recited a war poem.

M. Mourier, who spoke in the name of the French Government, opened the meeting, affirming Franco-American fraternity and the feeling of France that she was not only aided, but also comprehended by America. The work of the American Red Cross was the subject of M. Firmin Roz's speech. He was followed by Mme. Jules Siegfried, who spoke as an Alsatian and in the name of the innumerable widows and orphans succored by the American Red Cross. Admiral Touchard spoke on behalf of the French Red Cross which has profited so much by the liberality of the American Red Cross, and General Malleterre, after expressing his personal recognition of the work of the American Red Cross, said that he brought also homage of the French maimed soldiers.

Responding to the many tributes to the American Red Cross paid by these speakers, Mr. Davison said in short that it has been the privilege of the American Red Cross to have in those great world events a share, in which practically every loyal American takes honest pride. Because it is a voluntary organization, the American Red Cross was able to operate with greater speed than is possible for Governments and armies and to precede the American Armies to France, in anticipation of their arrival with an assurance that the heart of the American people was enlisted with the heart of France in the great cause. As soon as America entered the war the American Red Cross mobilized its forces and resources and hastened to assist the French forces and their families to make preparations for the American soldiers. The success of the endeavors has been due as much to the cordiality of the French reception and coöperation as to American enterprise. The great amphitheatre of the Sorbonne, in which the ceremony took place, was packed to the doors.

Mlle. Germaine de la Valette, head of the American section of the Press Department of the French Foreign Office, has been killed by the accidental explosion of a hand grenade. Mlle. de la Valette picked up the hand grenade while conducting a party of American women through the reoccupied territories on the French front. It exploded with fatal results. A French officer with the party had an arm blown off. He had warned the members of the party to touch nothing.

Miss Julia Stimson, Chief Nurse of the American Red Cross in France, has just been appointed Chief Nurse of the Army Nurse Corps of the American Expeditionary Force. Her appointment took effect in the early part of November. Miss Stimson has been with the Red Cross since April, 1918. For ten months previously she had been serving at British General Hospital No. 12, with Base Hospital

Unit No. 21, which was one of the six hospital units to be assigned to the British forces just after American intervention. Miss Stimson joined the unit a year before our declaration of war, while she was still serving as head of the Washington University Training School for Nurses, in St. Louis.

5. Back Injuries and Their Relation to the Workmen's Compensation Law.—Joseph C. Scal refers to the difficulty of diagnosing correctly injuries of the back, the most successful of all malingerers being the workman who claims such injury, and he points out that since the Workmen's Compensation Law has been in effect more back injuries among workmen have come to the attention of the profession than ever before and that a long course of energetic treatment is required before the patient will resume work. Pain in the back may be caused by lumbago, in which case it is usually unilateral, relieved by pressure, and especially acute with movement. Kidney conditions, tumors, and uterine displacements should be eliminated before a diagnosis of lumbago is made. Pain may be caused by overtaxation of a muscle for a long period of time, when there is generally a temporary loss of full contractile power, in which case patient's description is of great value; a throbbing pain indicates pus; a dull, boring pain means pressure increase on a deep local part, as in osteomyelitis; a constant annoying pain means hyperemic inflammation, while a burning pain indicates that the skin only is involved. In strained back the muscular tissues have been overtaxed beyond the physiological limit; in this condition it should be noted that a painful muscle is painful only when that muscle is thrown into action and, therefore, an injured man should be asked to place himself in the exact position he occupied at the time of the accident. This will undoubtedly cause pain and prove the veracity of the man's statement. Pain in a strained muscle has an acute onset and should get well in from two to three weeks, provided no complicating focus of infection exists in some other part of the body; in the latter case the pain diminishes with rest, but reappears with exercise until the infecting focus is eradicated. Rupture of the muscles—another possible cause of pain—is rare, but may result from the force of opposing muscles brought suddenly into play. External force or violence may result in contusion of the muscles, and if severe may cause temporary muscle paralysis; in permanent paralysis the injury is to the nerve and not to the muscle. Straining of ligaments results in an effusion of blood into the joint or surrounding tissue and causes overdistension with resultant pain. Pain in the bones of the back is generally due to bone disease, such as tumors or syphilis, when the pain is worse at night. In fractures, when impacted, no pain may be present—particularly in spinal fractures. If the lesion is in the vertebral or intervertebral joints, pain will result if the patient rises on his tiptoes and comes down suddenly on his heels. Sacroiliac sprains are infrequent and are usually due to severe falls or wrenching. The symptoms are localized pain on pressure, increased by walking, sitting, or rising. Treatment indicated is absolute rest, obtained by strapping the pelvis and later by applying an elastic belt, local remedies, hot applications, massage, etc. In injuries involving the spinal cord, there is gradual onset of paralysis from hemorrhage. If the cord itself is involved, paralysis is immediate and more or less permanent. In fracture of the spine, if the cord is not affected, there is often absence of symptoms. With involvement of the cord, there is definite corresponding paralysis of the nerves that pass through that location. In "railway spine" no actual damage exists, the symptoms coming on weeks after the accident and persisting until litigation is at an end. Weakness of the back is a purely subjective symptom, and in the absence of local nutritional disturbances, it is fair to assume that exercise in the form of light work will be more beneficial than harmful. Stiffness of the back may be due to muscular spasm or structural changes. The author adds that in examining alleged painful backs in patients suspected of malingering, he has found it advantageous to mark the spot indicated as painful with a blue pencil; then, after distracting the patient's attention, to ask him again to indicate the spot. If he is malingering, the second spot indicated will be a few inches away from the first.

3. Pollakiuria as a Functional Disturbance Due to Eyestrain: Causes of Excessive Frequency of Micturition.—W. W. Kahn points out the importance of a strict differentiation between polyuria and incontinence of urine and pollakiuria, or excessive frequency of micturition. He concludes from his observations on 1,500 cases that in a great percentage of cases pollakiuria is a neurosis, brought about by malfunction of a distant organ, especially the eye, and he reports two cases in which pollakiuria was found to be caused by eyestrain. These cases led him to make a systematic inquiry as to the frequency of micturition in refraction cases which came under his observation, with the result that of 1,500 cases, 316 (140 men and 176 women) were found to be suffering from pollakiuria. In this series the percentage of recoveries in women was twice as large as in that of the men, a fact attributed by the author to the greater nervous instability in women. Kahn concludes from his observation of these cases that the frequency of pollakiuria as a neurosis is immensely larger than has been thought, and that, contrary to the general medical opinion, the condition is nearly as frequent in men as in women. He is of the opinion that pollakiuria as a symptom of eyestrain is due to two causes: the local pathological change in one of the urinary organs and hyperirritability of the nervous system caused by eyestrain. If the local lesion is slight relief of the nervous system will effect a cure. Before a surgical interference is tried, this author believes that a careful refraction should be indicated in all cases of pollakiuria, unless the operation is necessary for some reason other than excessive frequency of urination. Although the disturbing cause in his series of cases was eyestrain, he would not exclude malfunctions of other organs from having similar effects.

2. War Nephritis: A Clinical Study of Early Cases.—Major H. B. Day points out that the course of war nephritis is marked by more or less evident changes at regular intervals of five to six days, a periodicity which is also exhibited in trench fever, but in no other disease prevalent in the war. The question therefore arises: Is war nephritis a complication of trench fever? Certain cases of war nephritis do show all the signs of trench fever, but such cases are infrequent enough to be mere coincidences. On the other hand, mild types of trench fever are extremely prevalent, and the liability of trench fever to recur months after apparent recovery is notorious, particularly after exhaustion or chill, exposure to poison gas, or receiving a wound; and this may happen to patients who have no recollection of previous fever. In such cases chronic enlargement of the spleen is usually present. However, when we consider the identity of the diseases from a closer aspect, we are confronted by points of difference: (a) Ordinary and experimental cases of trench fever, as studied in the wards, show little or no tendency to develop nephritis; (b) there is no proportion between the severity of the fever in war nephritis and the degree of renal damage—many severe cases of nephritis show no definite damage; (c) war nephritis has a seasonal variation which is not apparent in trench fever. In ordinary cases of trench fever albumin, often accompanied by microscopical amounts of blood, is often present in the urine during the initial stage; and certain patients show a remarkable oliguria independent of the pyrexia and possible early albuminuria. The urinary flow may be almost suppressed for from twelve to twenty-four hours, or there may be a marked reduction for several days, or a moderate quantity of low specific gravity urine without albumin may be passed after fever has subsided. Under unfavorable circumstances, the renal injury may progress to actual nephritis. Although there is a close similarity between the general features of the two conditions, war nephritis is distinguished by a definite periodicity, the seasonal incidence pointing to cold and exposure as predisposing agents. These factors may well turn the scale in trench fever, since a large proportion of milder cases do not report sick; consequently, they are exposed to cold and wet and continue on a full meat diet, with the result that considerable strain is thrown on kidneys injured by trench fever infection, resolution is impossible, and nephritis results. Whether or not the coincidence observed between the two diseases depends on an identical infection can only be satisfactorily settled by experimental and laboratory work.

5. A Routine Treatment for Septic Sores and Nile Boils.—Captain H. Warren Crowe is of the opinion that the septic sores which have been common from time to time among troops in Egypt, in Salonica and Mesopotamia, are due to some cause associated with a hot, dry climate or special dietary, and that the lesion produced is infected with the prevailing microbes. Nile boils, which have also been prevalent in these armies, he believes to be caused by a white staphylococcus allied to the *S. epidermidis albus* of the skin. He believes that the great majority of these cases can be cured by vaccines used in conjunction with certain surgical measures, which he describes. The vaccines are prepared as follows: *Septic sore vaccine.*—Cases showing freely discharging superficial sores are chosen. A sore is cleaned up with alcohol; exuding serum is taken up in a sterile pipette and dropped into Wright's pneumococcus broth; after twenty-four hours' incubation, the broth is shaken up and examined microscopically, when it will be found to contain streptococci, 2,500 million to the c.c. Lysol to make ½ per cent. solution is mixed with the culture, and twenty-four hours later the sterile culture is poured into a stock bottle. *Boil vaccine.*—A series of typical young boils in different patients are cleaned up with alcohol, the head lifted, and serum made to exude by means of a heated test tube; subsequent procedure is the same as for the septic sore vaccine. The two stock bottles are then capped with rubber caps, paraffined, thoroughly shaken up, and tested for sterility, and from them a lower strength stock containing 400 million of *each* vaccine to the c.c. is made. For use in treatment the following dilutions are needed: two million, eight million, and thirty-two million to the c.c. of each vaccine, according to the syringe to be used. The vaccine is given in bi-weekly doses of 500,000 until all lesions are cured, no fresh ones appear, and no old superficial scars start weeping afresh after an inoculation. The author has found that the small doses, which are the best for cure, have no effect in preventing relapse, and that the omission of even one dose is frequently followed by a fresh outbreak. It is essential to continue the vaccine when cure is apparently complete, with increasing doses for prophylactic purposes. After-treatment should consist in giving doses as follows: one million, two million, four million bi-weekly, then at intervals of seven days, eight million, sixteen million, thirty-two million.

3. Treatment of Ante-Natal and Post-Natal Syphilis.—John Adams reports the results of treatment of thirty cases of pregnant syphilitic women at the Travies Inn Venereal Centre for Pregnant Women, London, which he points out is the first, and at present, only hospital of its kind. Disregarding patients suffering from gonorrhea, since the hospital was opened thirty cases of syphilis have been admitted and these cases furnish the basis of the author's remarks. On admission to hospital a Wassermann test is done, and as soon as syphilis is diagnosed treatment by one of the salvarsan substitutes is commenced, combined with intramuscular injections of grey oil, 40 per cent. B. P. C. emulsion. The salvarsan substitutes used have been galyl and novarsenobillon, galyl in glucose solution being used exclusively for babies. Having the highest opinion of salvarsan for the treatment of syphilis, the author also considers the administration of mercury of the greatest importance, but believes that the methods advocated are not wholly satisfactory. Immediately on the birth of a child a specimen of blood is taken from the vessels of the divided umbilical cord in a cubic centimeter glass tube, and a similar amount of the mother's blood is secured for the purpose of a Wassermann test. A small portion of the placenta is also obtained for examination for spirochetes. Should further specimens of the child's blood be required, from a quarter to half a cubic centimeter is obtained by pricking the heel with a medium sized Hagedorn needle in three or four places near together and letting the blood drip into the glass tube; if necessary, this should be repeated at intervals of a month or six weeks. In this series of cases, the author has been impressed most of all by the large doses which newly born infants have been able to take and the excellent results which have ensued. Adams concludes that: (1) Syphilitic pregnant women can be treated with salvarsan, even up to the day of their confinement, with safety and every advantage. (2) A mother whose blood gives a positive Wassermann reaction may, after treatment, be delivered of a child whose blood gives a negative reaction. The child may continue to thrive and give a negative

blood test. (3) Syphilitic children can safely be treated by salvarsan immediately after birth. (4) Salvarsan, combined with treatment by mercury, has a more certain and quicker action in producing a negative Wassermann reaction in the child than in the mother. (5) In nearly all syphilitic children born alive, treatment can convert a positive Wassermann reaction into a negative, and such children appear to become healthy and show a regular weekly gain in weight. (Between a syphilitic mother and a child who gives a negative Wassermann reaction at birth the placenta seems to act as an interceptor of syphilitic virus, probably brought about by the chorionic ferments.)

Berliner klinische Wochenschrift.

September 30, 1918.

The Splenic Functions in Man.—E. Blumenfeldt reviews some of the procedures proposed for estimating the extent of preservation of the spleen and its functions, such as the injection of adrenalin, which should produce a temporary lymphocytosis on account of the resulting contraction of the unstriped muscle fibers of the organ with the consequent expression of numerous lymphocytes, the changes in the cell resistance to hypotonic solutions, or the presence of nuclear débris in some red corpuscles. These various methods were applied to a subject who had undergone a splenectomy three years and a half previously, on account of a traumatic lesion of the organ. The results were negative, in as much as the reactions of the organism were those of a healthy subject possessing his spleen. In the case of injections of adrenalin particularly, a leucocytosis with a relative lymphocytosis resulted, just as is met with in any normal subject. The writer therefore concludes that there exists an insufficiency in the above mentioned diagnostic methods. This fact is, for that matter, not to be wondered at, since the spleen is not a unique organ which cannot be replaced, but is in fact part of a lymphatic system extending over the entire body and all its composing elements may undoubtedly assure the functions of the missing spleen perfectly.

A Case of Temporary Cyanosis Without a Valvular Lesion.—W. Augenete gives a detailed description of the case of an infant who, slightly cyanotic during the first few days, became intensely so between the fifteenth and twenty-fifth days after birth. From this time on the child, who also developed eclamptic seizures, became perfectly normal. At no time did cardiac auscultation reveal a single abnormal sign. The writer is of the opinion that the case was one of an interventricular communication with a slight pulmonary stenosis. The appearance and disappearance of the cyanosis were related to the tension in the two sides of the heart. The effect of various treatments essayed corroborate this influence of the differential pressure in the two hearts on the mixture of their blood and the resulting cyanosis.

Münchener medizinische Wochenschrift.

October 1, 1918.

Clinical and Experimental Researches on Hemolytic Icterus.—H. Lüdke offers an exposé of the present-day conceptions of this subject and, what is extraordinary, gives full credit to French writers. He records four personal cases characterized by icterus, anemia, diminished globular resistance, and tumefaction of the spleen with or without tumefaction of the liver. The icterus was of the acholuric type and the blood serum contained bilirubin but no urobilin. For that matter, generally speaking, the bilirubin of the blood does not pass into the urine unless there is a high concentration, while urobilin passes through the renal filter with greater ease. The urine contains urobilin in hemolytic icterus, especially in the acute types. The feces were acholic in the four cases observed by the writer and only assumed their normal color during the hemolytic paroxysms. As to the anemia, which only involved the red corpuscles, Lüdke noted that the blood offered the usual changes of secondary anemia. He did not constantly observe the granular red cells, mentioned by Chauffard, in this affection. The resistance of the cells was especially evident when the procedure of hemolysis of displasmatized blood was employed. The resistance to saponin did not offer any typical change. The writer was also able to observe the presence of isolysins in all four cases, while the autolysins were less constant. He also studied the question as to what extent these substances could be considered as the cause of the hemolysis in his patients. He was able to experimentally verify the production of these substances in dogs under certain conditions after injection of this type of red corpuscle. Lüdke concludes in favor of the probable etiological part played by the autolysins in the genesis of hemolytic icterus. These substances probably develop at the time of the paroxysms of anemic icterus and their production is more particularly splenic.

Periodical Vomiting or Periodical Acetonemia?—F. Hamburger is of the opinion that this form of vomiting is not the result of acetonemia, but is, on the contrary, the cause. He founds his belief on a personal case in which the acetone in the urine only increased the day following the paroxysms of vomiting and on the ease with which acetone appears after symptomatic vomiting, such as occurs in meningitis or appendicitis, for example.

Deutsche medizinische Wochenschrift.

October 3, 1918.

The Gastric Secretion in War-Time.—L. R. Grote has noticed, besides a relative increase in the number of gastric cases in general, a serious increase of cases of hyperchlorhydria. As the writer's cases were among both country and city people, insufficient or poor food cannot be the cause of this phenomenon. Hyperchlorhydria of wartime has been noted by a number of observers. It has been attributed to the abuse of coffee and tobacco, but Grote does not admit either of these etiological factors, believing that the syndrome of the hyperacidity is due to an exaggerated sensibility of the gastric nerves. Therefore the best treatment consists in the internal exhibition of cocaine and a 2 per cent. silver nitrate solution. These patients do not enter into the class of true gastropaths, but should be regarded as possessed of neuropathic states.

The X-Ray Treatment of Graves' Disease and Malignant Goiter.—P. Sudeck studies the indications of radiotherapy in these two morbid processes. In the goiter of Graves irradiation is insufficient, unreliable, and even dangerous on account of the possibility of thyroid and parathyroid atrophy. On the other hand, radiotherapy may serve as a preliminary to operative interference in cases where the gravity of the disease is a contraindication for an immediate operation. In malignant goiter the results have been most encouraging, to such an extent that the success must be regarded as much due to a particular susceptibility of the neoplastic tissue as to the superficial situation of the growth. The writer has not noted that any particular type of neoplasm (carcinoma, sarcoma, sarcocarcinoma) reacts better than the others. Inversely, the surgical treatment of these malignant goiters is unsatisfactory. The necessity of performing total extirpation and at the same time saving the parathyroids makes radiotherapy preferable to operation in malignant disease of this gland.

Studies in Chemiotherapy in Chronic Malaria.—F. Kalberlah and H. Schlossberger have experimented on the action of certain dyestuffs which are efficacious in the trypanosomiases and metallic compounds of salvarsan in chronic malaria without any practical results.

Wiener medizinische Wochenschrift.

September 7, 1918.

Reform in Medical Instruction.—E. Franz offers a contribution on this subject, which appears to considerably occupy the minds of the Vienna profession, of really practical import. He proposes the following schedule of study: Four terms of anatomy, physiology, chemistry, and biology; four terms of practice in different clinics; two terms given up to theoretical lectures. Teaching should comprise only matter that is really useful and necessary for the student. The examinations in each branch should be held by two pro-

fessors at the same time in order to limit the questioning to well established facts. The writer, who makes some very interesting remarks relative to his plan of instruction, does not, however, tell us how this system of study will permit the recruiting of a scientific teaching corps.

The Treatment of Addison's Disease.—P. Leitner has observed a case of "essential" Addison's disease of the most typical sort cured by the exhibition of capsules containing fresh suprarenal gland at the dose of one, two, or three capsules daily. Recovery resulted in the disappearance of the pigmentation and a gain of 28 pounds in weight, as well as the disappearance of the anemia. Adrenalin glycosuria, negative before treatment, afterward became positive. It is to be noted that the gastric achylia present before treatment was begun was in no way influenced by it. This case adds one more to the number already reported by Strümpell of Addison's disease cured by suprarenal opotherapy.

La Presse Médicale.

September 23, 1918

Lethargic Encephalitis.—Sainton recalls that last spring Netter drew the attention of the profession to an epidemic affection which had already prevailed in Austria and had apparently broken out in Paris. The English neurologists now announced that a similar malady had been seen in their country, where it had been diagnosticated botulism. The total number of French and English cases at latest accounts was seventy-one, about equally divided. It has, therefore, become possible to draw up a formal exposition of the disease and the author has had some personal material on which to draw. He sums up by stating that the leading symptoms are somnolence or lethargy, paralyses or pareses of the nerves of the mesencephalon, notably the motor nerves of the eye, and a febrile infection. The process is a more or less diffuse encephalitis predominating in the mesencephalon. Any age may be attacked, but it is far more common in the adult. The initial symptoms are chills and fever, headache, prostration, vomiting at times. Apparently there are two or three weeks of prodromes of an equivocal character. The mental state combines hypersomnia with lethargy, for when roused with difficulty from sleep the lethargic state is completely in evidence. Cema never develops save in fatal cases. In certain cases the patient cannot be roused at all. If the lethargy is not obvious when the patient is aroused the movements are automatic. Somnolence may not be incompatible with nightmares and an oniric delirium. In some cases after consciousness has once returned it may again be lost. During convalescence the patient may show narcoleptic crises. A certain type of amnesia is evidently present, as the patient has not the slightest idea how long he has slept. The mortality has been from 4 to 35 per cent., the low figure occurring only in the Austrian cases, which may conceivably differ from the others. The diagnosis of this affection could not of course be made at first, and it was mistaken for typhoid fever, pneumonia with delirium tremens, acute meningeal tuberculosis and cerebrospinal meningitis. The closest similarity is to the latter. All of these remedies can be excluded. The malady was heard of during the influenza pandemic of 1889-90, when it was in part regarded as of grippal origin, an influenzal poliencephalitis. This possibility has not yet been cleared up, and it is certainly singular to see the recrudescence appear in an influenzal year, but the bacteriological proof is wanting. The possibility of botulism is not to be thought of in the French cases, however suggestive it may have been to the English observers.

Correspondenz-Blatt fuer Schweizer Aerzte.

August 24, 1918

Autopsy Finds in Influenza Cases.—Glaus and Fritzsche (Basle) have made autopsies on 53 cases of influenza, of which 38 were in male and only 15 in female patients. The ages ranged from 19 to 30 years in 41 of the 53. The limits of age were one year and 59 years. In 40 of the subjects the general condition, aside from the ravages of the disease, was perfect. It may have been a coincidence that six of the women were pregnant. Three women had aborted, and in the others the fetus was dead and macerated. Four patients, including two pregnant women, had mitral stenosis. Three of the victims were tuberculous. There were several others with emphysema or other chronic lung affections, so that the chief predisposing factor was cardiopulmonary disease, a fact readily comprehended. In regard to the ravages of the disease proper, there was a type of lung which predominated —the large piebald or motley-colored lung, condensed for more or less of its mass, with diminished air content. Incised, this tissue oozed foamy, blood-tinged fluid, and the section showed a mixture of hemorrhagic, pneumonic, necrotic or abscessing form of lung tissue. Amid these were stretches of a relectatic or permeable lung substance. Some of the foci were infarcts. Some of the subjects, instead of the preceding picture, showed a more typical broncho-pneumonia. The bacteriological examination showed the presence of the diplococcus lanceolatus in 45 cases, in 17 of which the same germ was cultivated from the heart's blood. Other germs showed much less constancy, and Pfeiffer's bacillus was conspicuous only by its complete absence. On account of the presence of the usually found morbific germs, pneumo-, strepto-, and staphylococci, in sufficient numbers, despite the inconstancy of any one form, the authors held all three responsible for the fatalities, acting in concert. Apparently the mixture of infection did not obtain in the individual patient but only for the epidemic *per se*.

Hygiea.

July 31, 1918

Treatment of Diabetes with Prolonged Fasting.—Arnell emphasizes the importance of diet fat in the genesis of acidosis, and gives an account of the principles and technic of the Joslin prolonged fast in the management of diabetes. The favorable influence of this plan is shown in a case history of a diabetic with strong acidosis tendency, who had withstood four attacks of coma in a year. Through prolonged fasting and withholding of fat in the nourishment the patient was rendered free from both sugar and acidosis and he was even rendered tolerant, to a limited extent, to carbohydrate. Moreover he obtained advantage through the fact that he no longer had to take daily doses of bicarbonate of soda (he had used from 20 to 100 gms. of this substance daily for two years at a stretch). The fasting treatment of severe diabetes is worth an augmented interest.

Case of Chylothorax.—Gullbring reports a case of chylothorax in a boy of 13 with far advanced tuberculosis, the phenomenon being in evidence shortly before death. The chemical composition of the pleural fluid corresponded well with that of chyle—albumin, 4 per cent.; sugar, 2.4 0/00 (or 0.24 per cent.); fat, 1 per cent. At autopsy no cause could be found for the exudate, and the author had to conclude that there was an abnormal permeability of the chylous radicles which run along the pleura.

Operative Treatment of Bladder Tumors.—Neander states that from 1901 to 1915 the surgical clinic of the Seraphine Hospital supervised 49 cases of vesical tumor, of which all but 7 were submittd to operation. Of the 42 operative cases, the intervention was palliative only in 11, and of this number 5 deaths resulted. There were therefore 31 radical operations for the following: Carcinoma, 9 cases; sarcoma, 2 cases; quasi-benign tumors, 20. Of the 9 cancer patients, 2 died of the operation, 4 soon suffered relapse, and the other three still live in good health after 9 or more years. One of the two sarcoma patients is also living. Of the 20 patients with quasibenign growths, 9 have died of recurrence and 3 have had relapses treated and still live. Five others are symptom free, and one said to have relapsed has not been seen. The author likes Squier's operation for bladder tumors, and apparently oudinisation has been used only for certain recurrences when beginning. Radium results are not encouraging, but one excellent result is set down to röntgen rays in controlling recurrence.

Book Reviews.

RADIO-DIAGNOSIS OF PLEURO-PULMONARY AFFECTIONS. By F. BARJON. Translated by JAMES A. HONEIJ, M.D., Assistant Professor of Medicine in Charge of Radiography, Yale Medical School. Price, $2.50. New Haven: Yale University Press, 1918.

THIS volume comprises 175 pages of text, over 50 radiographs, and 27 other illustrations. The five sections are devoted respectively to methods of examination, study of the pluræ, study of the bronchi, study of the lungs, and projectile wounds. The present volume is a most faithful translation, with reproduction of all illustrations. The translator has confined himself strictly to his task, refraining scrupulously from the temptation to edit the work. Such impersonalism is rather rare in these days, but we are not sure that it is not the proper course to pursue in the case of a work of such excellence as this.

THE HODGEN WIRE CRADLE EXTENSION SPLINT. The Exemplification of This Splint with Other Helpful Appliances in the Treatment of Fractures and Wounds of the Extremities and Its Application in Both Civil and War Practice. By FRANK G. NIFONG, M.D., F.A.C.S. With an Introduction by HARVEY G. MUDD, M.D., F.A.C.S. Pp. 162 with 124 illustrations. Price, $3.00. St. Louis: C. V. Mosby Co., 1918.

FOLLOWING chapters on pertinent anatomical facts and on fractures of the femur, the author discusses splints of various kinds and for various purposes, such as splints for immobility, for immobility and extension, for immobility and ambulation, and for immobility, extension, and suspension, finally devoting elaborate attention to the Hodgen splint and its use. The author finds something good in many of the splints in use before, or developed during, the war; but for him the Hodgen splint is so simple of application and so efficient that there is but little room for any of the rest. In fact, he appears to think that the best of the newer devices are merely more or less complicated elaborations and their value depends largely upon the fidelity with which they follow the fundamental principles of the Hodgen splint. In this he is to a certain extent correct; for Hodgen may well be called the father of the suspension-extension principle in the treatment of fractures of the femur. The book is well written, is profusely illustrated, and is very practical.

SURGICAL CLINICS OF CHICAGO. Volume 2, Number 1, February, 1918. Pp. 226, with 73 illustrations. Published bi-monthly. Price, per year, $10.00. Philadelphia and London: W. B. Saunders Co., 1918.

THIS volume contains sixteen clinical lectures, one of which, on gunshot wounds of the head, was given by Major Kellogg Speed at one of the hospitals of the British Expeditionary Force. There are an unusual number of interesting clinical lectures in this issue. Among these we may mention that by Andrews and Mix on duodenal ulcer; Bevan's remarks on gall-stone ileus; Eisendrath's lecture on varieties of ureteral strictures; Vaughn's on acutely strangulated intra-abdominal tumors; and one by Straus on acute ileus. There are also lectures on bone and joint surgery and on other subjects.

BIPP TREATMENT OF WAR WOUNDS. By RUTHERFORD MORISON, Professor of Surgery, Durham University; Senior Surgeon, Northumberland War Hospital. Pp. 72, with 9 illustrations. Price, $1.00. London: Henry Frowde, Hodder & Stoughton, Oxford University Press, 1918.

THIS excellent little book was written by request as a war contribution and gives a concise description of the composition, technique of application, and clinical experiments with Bipp, its uses and limitations in the various types of wounds, such as fractures, sinuses, and chronic bone cavities, joint wounds, amputations, injuries to the soft parts, etc. "Bipp" is composed of bismuth subnitrate, 8 parts; iodoform, 16 parts; liquid paraffin, 8 parts, or a sufficient quantity to form a thick paste.

In writing this book Morison endeavored to avoid two difficulties: first, an explanation of results which he knew would plunge him into ventures from which he could not escape unscathed; second, "to avoid any overestimation, from excess of enthusiasm, of the value of this method of wound treatment." Hence, he limited the information offered to what he knew and rejected any other matter, however interesting it might be. He has given the facts, therefore, as the treatment has been developed by him and his associates in the handling of several thousand cases at the Northumberland War Hospital. He admits the possibility of iodoform or bismuth poisoning, but believes that such cases rarely develop when Bipp is used at the proper time, in the proper quantity and with the proper technique. He considers the method "so simple that a clever surgeon is unnecessary for the achievement of the best results, though a *careful* one is."

SYMPTOMS AND THEIR INTERPRETATION. By JAMES MACKENZIE, M.D., LL.D. (Aber. and Edin.) Lecturer on Cardiac Research, London Hospital; Physician to the Mount Vernon Hospital; Consulting Physician to the Victoria Hospital, Burnley. Third Edition. Price, $3.75 net. New York: Paul B. Hoeber, 1918.

IF a physician is content to practise medicine by symptomatic, empiric, specific, and diplomatic methods, there is no reason why he should add this book to his library. If, on the other hand, his is the type of mind which searches behind effects for causes and from the symptom seeks to visualize the disordered physiological process itself with its meaning to the patient, he will read this book with a keen intellectual delight. Dr. Mackenzie's study of pain in all its relations to diagnosis and treatment is unsurpassed and his account of cardiac abnormalities, especially as they affect the patient's well-being, should be read by every general practitioner, especially these days, when he may be called upon to pass upon the effect which some irregularity of the heart may have upon military service. In the present edition Sir James has included two valuable appendices, one on hyperalgesia in abdominal disease and an especially suggestive one dealing with clinical investigation.

IL COLPO DI CALORE. By Dott. SALVATORE GUNGI. Catani: V. Giannotta, 1915.

THIS work on heart stroke was written before Italy had entered into the war. The scope of it is universal —insolation as seen in all geographical areas. Much book research has been necessitated and the large bibliography seems to be legitimate, made up of works actually consulted. As recent monographs on this subject are rare—almost nonexistent—this volume might be worthy of a translation into any one of the current tongues.

ANATOMY OF THE HUMAN BODY. By HENRY GRAY, F.R.S., F.R.C.S., Lecturer on Anatomy at St. George's Hospital Medical School, London. Twentieth Edition thoroughly Revised and Re-edited by WARREN H. LEWIS, B.S., M.D., Professor of Physiological Anatomy, Johns Hopkins University, Baltimore, Md. Illustrated with 1,247 Engravings. Price, cloth, $7.50. Philadelphia and New York: Lea and Febiger, 1918.

SURELY a book which has enjoyed an uninterrupted existence of 60 years (the first English edition of Gray's Anatomy appeared in 1858) and has appeared in a new edition at an average of every three years has been so thoroughly reviewed as to leave little to be said. The older generation of medical men were brought up on Gray, and though other more modern works now dispute its old-time supremacy, these men still look back with affection to this, their first text-book. Its face has so changed with time, however, as in many sections to be unrecognizable. It is only in the section on Osteology and in isolated places here and there that one sees the familiar illustrations—rather ugly but more informing than many of the new and in part colored pictures which have replaced the original ones. The text also has been extensively altered, although some of the descriptions of the first writer still exist. Much that is new relates to histology, which is the major part of anatomy that has advanced in the three score years that have passed, though the Basle anatomical nomenclature also would trouble Henry Gray if he should happen to reincarnate as a medical student and try to pass off his old knowledge on an up-to-date State medical examiner.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held October 28, 1918.

THE PRESIDENT, DR. HOWARD CANNING TAYLOR, IN THE CHAIR.

Executive Session.—Dr. JOHN P. DAVIN introduced a resolution requesting the Health Department not to hold physicians strictly accountable to the letter of the law requiring the prompt reporting of cases of infectious disease, inasmuch as many physicians were working under such pressure during the epidemic of influenza that they did not have time to make up their reports promptly.

Dr. FREDERIC E. SONDERN opposed a motion to refer these resolutions to the Comitia Minora on the ground that it would put the society on record as seeking to evade or break a law.

Dr. DAVIN replied that the resolutions did not ask any one to perform an illegal act, but simply asked mercy for the hardworking physician who found it a physical impossibility to report his cases of influenza promptly.

On motion these resolutions were laid on the table.

Dr. ABRAHAM J. RONGY called the attention of the Society to the advisability of issuing a warning to pregnant women urging them to isolate themselves during the present epidemic, since they were peculiarly susceptible to the disease. In the presence of influenza there was a great difference of opinion as to whether or not it was advisable to induce labor. In order that the obstetrician and the general practitioner might have some guide in deciding this question, he moved that a committee be appointed to make an investigation, and if possible, express an opinion on this point.

Dr. J. MILTON MABBOTT expressed the opinion that it would be unwise for the County Medical Society to lay down a rule of practice for all cases. He thought it unnecessary for the Society to take up the matter as the law now gave any physician the privilege of calling in a consultant and, if both were agreed that the induction of labor was indicated, the pregnancy could be terminated, so there was no need for the Society to take any action on this question.

Dr. J. RIDDLE GOFFE said it would be difficult for any committee to lay down hard and fast rules that would cover all cases. Each case had to be decided on its own merits. He hoped the motion would not be approved by the Society.

This motion was lost.

The Present Status of the Influenza Epidemic in New York City.—Dr. ROYAL S. COPELAND, Health Commissioner, made this address, by invitation. He reviewed the measures that were being employed by the Health Department to combat the epidemic and quoted figures to show that New York had fared far better than other large cities of the United States. He said he was sure that no overworked doctor would be sent to jail because he had not reported his cases of influenza as promptly as he would ordinarily be expected to do. From September 14 to October 19, there had been in 46 States a total of 35,000 deaths from influenza and pneumonia. In addition to this there had been about 15,000 deaths from these diseases in the military camps in this country, making a total of about 50,000 deaths which were attributable to the epidemic. In some localities the epidemic had not yet reached its highest point, while in others it was on the decline, and he believed that in the course of a week a definite decline would be observed in this city. The figures of the Health Department gave no actual index as to the prevalence of the disease, for there had been no complete reporting of cases. Dr. Copeland explained that the reasons why the Health Department wished to have as complete reports as possible was in order that it might concentrate the forces of its own staff and those of the various social agencies in those districts in which the disease was most prevalent. To date about 101,000 cases of influenza and 13,260 cases of pneumonia had been reported. It was found that in the Army the mortality from influenza averaged a little over 4 per cent. In civil communities the mortality rate was considerably lower. Making allowance for the deaths that under ordinary conditions would have occurred from pneumonia during the period of the epidemic and for the deaths of Navy men of whom there had been a considerable number cared for by the hospitals of the city, it was estimated that the mortality in New York City from influenza was 2½ per cent. Reckoning on this basis there had been probably about 500,000 cases of influenza in New York City since the beginning of the epidemic. In other words, about 10 per cent. of the population had been affected, whereas in many communities as many as 25 to 40 per cent. of the population contracted the disease. The death rate in some cities had reached appalling proportions during the height of the epidemic. In Philadelphia it was 150 per 1,000 population; in Boston 101, while in New York it was 50. Dr. Copeland spoke of the organized emergency relief work, which he said was important and interesting, not only because of what it was doing during the epidemic, but because it marked the beginning of a new activity on the part of the Health Department. There was no provision by law for work of this kind on the part of the Health Department, but it seemed that in the present emergency they were justified in entering this field, and they were now planning to make at least the skeleton of such an organization permanent, so that in case of emergency it could quickly be put in operation. There should be a number of community centers that could distribute clothing and food, where advice could be obtained, and from which investigators could quickly go over the district and cover the city. If necessary the city should support such centers.

Dr. JOHN H. BRANTH said that it was very laudable indeed that our Health Commissioner should come here to discuss with us measures regarding the existing epidemic. Regarding the treatment of the present scourge we had not fully scratched the surface. Surely one was struck by the fact that this influenza led often to a pneumonia which was rapidly fatal. The bacteriologist should find the reason for this. It must also be recognized that disease and its phases could not be worked out entirely in the laboratory; bedside observation was still a factor in diagnosis. The invasion of the Pfeiffer bacillus, which was credited with being the cause of former influenza epidemics, and by some was claimed to be the cause of the present scourge, was not then followed so often by fatal pneumonia. There must be in the present epidemic another factor not present in former epidemics. Could it not be that breeding with other microbes, as the pneumococcus, etc., was the cause of this virulence? There was no doubt that some microbe was at the bottom of this epidemic. It was stated that the microbe was an anaerobe, living in moisture and darkness. Sunlight and pure dry air destroyed it. The surgeon and physician in fighting such an invading enemy used bactericides and cleanliness, both of which were helpers to the always working phagocytes. At all times those who knew medicine depended upon the action of the phagocytes in combating invading microorganisms; if their action was too weak, then, and then only, was an invasion by an enemy possible. In applying remedies we must respect the fact that the individual cell life of higher organisms was more vulnerable than the cell life of lower organisms. It had been discovered that the influenza microbe entered by the upper air passages. If it entered the mouth, it was met by a surface which was always bathed in saliva; the latter contained ptyalin, a very destructive agent for nearly all microbic life. So it seemed possible, to the speaker at least, that this route was not a frequent channel of invasion, except the mouth was not kept clean. The tears flowing from the lacrymal gland over the eye-ball and finally reaching the nostril through the nasal duct contained no such destructive agent as ptyalin. In fact, all the conditions in the nose favored the rapid multiplication of microbic colonies. In medicine they had found that the mercurials were the best bactericides. Why should these mercuric mixtures not act as well in cases in which there was an invading enemy in the nose as they did when directed against invading organisms in other parts of the body? The speaker had on many occasions advised the following: A mixture of 15 to 20 grains of yellow oxide of mercury in one ounce of lanoline to which a little pix liquida was added. This

was applied with the little finger as high up in the nose as possible. The salve "Aseptinal" acted as well but as this was a patent article a regular physician was not likely to prescribe it. A thin coating of the above ointment resisted the invader. Two to four applications of this ointment should be made daily. It was very essential that the natural functions of the body be kept near par and it was especially important to avoid fatigue, for upon these factors the activity and efficiency of the phagocytes depended. Mixed vaccines and serums offered another line for the stimulation of phagocytes which attacked and destroyed the microbes that had invaded the body.

Dr. BEVERLEY ROBINSON said that perhaps he was trespassing on time not supposed to be given to this subject, but he could not forbear calling attention to a remedy that he had used for coughs, colds, and influenza for many years, and which he had found more effective than any other remedy. This was salicylate of ammonium. He might add that this was particularly effective in preventing influenza. The dose depended on the age and condition of the patient, from five to ten grains in solution with a little pepsin where the patient was really ill and could remain at home. When used simply as a preventive it might be administered in capsule form. Dr. Robinson said that in a recent number of the *New York Medical Journal* reference was made to an article by E. B. Turner who gave his experience in 2,000 cases of epidemic influenza in which he found that salicin was the best remedy that could be given. The speaker had used salicin and diverse salicylates, and finally the salicylate of ammonium and could say that the latter was unqualifiedly the best and the least injurious.

Dr. L. W. ZWISOHN asked how a man was to make a diagnosis of influenza and report the case when the circumstances were as follows: A man was called to see a case and found the patient presenting only the symptoms of a slight cold. At the end of three days the patient would have no elevation of temperature, then suddenly on the third or fourth day he developed pneumonia. How could one report such a case as one of influenza unless he reported every case of cold?

Dr. COPELAND replied that it was sometimes very difficult to tell which were cases of influenza and which merely colds. All a physician could do was to report what he thought was influenza.

Treatment of Enteroptosis, Medical and Mechanical.—Dr. ANTHONY BASSLER presented this paper. (See page 1066.)

The Surgical Treatment of Intestinal Ptosis.—Dr. J. RIDDLE GOFFE presented this phase of the subject. After briefly reviewing the etiology of intestinal ptosis and discussing its relation to focal infection, he said that he believed that a frank confession from the general practitioner or internist would reveal the fact that the majority of his patients were suffering from some form of infection due to constipation or intestinal stasis. His prime business was to keep the alvine current moving, and to destroy the toxic forming bacilli of the intestinal canal. An extreme enteroptosis, when it had reached the stage of redundancy, persistent dilatation, angulation, kinks, and adhesions produced by stasis, afforded the most perfect culture tube for the multiplication of bacilli and the manufacture of toxins. These were the cases that required surgical interference to effect a cure either by stitching up the intestines, by an ileosigmoidostomy, or by complete colectomy. Not only must the intestines be secured in position, but the normal intraabdominal pressure re-established by diminishing, if necessary, the capacity of the abdomen when injured or relaxed and restoring perineal supports. The kidney, too, when displaced must be re-implanted to avoid drag on the flexures of the colon. The tests to apply to any operation were: (1) Did the operation meet the indications; relieve the condition and cure the patient? (2) Was it safe? That was, did it involve risks out of proportion to expected or actual benefits? The results as exemplified in the author's cases, if examined with an open mind, and discrimination, he believed, would not only justify, but commend the operation. Dr. Goffe said that his first experience with this operation was gained, in 1889, in the case of a young woman, 25 years of age, an expert stenographer and typewriter, a nervous dyspeptic and a neurasthenic wreck. She had a ptosed and dilated stomach. After treating her medicinally and washing out her stomach, morning after morning before breakfast, for weeks and months without improvement, she announced to the writer one day that she was tired of treatment and was ready for the operation which he had discussed with her some weeks previously. She entered the Polyclinic Hospital and was made ready for operation. Through a free incision above the umbilicus the anterior wall of the stomach was plicated with a row of sutures, parallel to the long axis. Just above this line two sutures were passed perpendicularly to it through the peritoneal and muscular wall of the stomach. Both ends of each suture were then carried up through the peritoneum and fascia of the abdominal wall, not through the skin, and made to appear each on its own side in the upper angle of the abdominal wound. After the closure of the peritoneum the two ends were tied, cut short, and buried in the closure of the abdominal incision. On putting the patient to bed the foot of the bed was elevated by putting a chair under it, thus securing what was familiarly known as the Trendelenburg posture. This was maintained for two weeks when the bed was gradually lowered to normal at the end of three weeks, the patient leaving the hospital at the end of the fourth week. Perfect success attended the procedure. The patient gained flesh and nerve power, returned to her work in three months, and continued it while under the writer's observation for several years. From this experience the author had gradually evolved the method he now employed in cases in which both the stomach and colon were involved in extreme ptosis with adhesions. By this method a procedure similar to that just described for the stomach was applied also to the transverse colon, and the hepatic and splenic flexures. The technique of this operation Dr. Goffe described and illustrated by lantern slides.

Dr. ARNOLD STURMDORF stated that within the last five years the treatment of enteroptosis has been the object of very intensive study by surgeons and internists; both recorded many successes, yet both experienced many failures by ignoring the fundamental causative factors of the condition. Normal visceral topography was the result of balance between the displacing force of intraabdominal pressure and the correct deflection of that displacing force by bony and muscular planes, presented within the abdominal cavity. The essential angle presented by these planes demanded correct skeletal and postural poise, neither of which existed in patients with enteroptosis. It followed that the therapeutics of the condition could deal with end results only and not with its etiology. Prolapsed abdominal viscera were normal and essential to these abnormal skeletal types. This was amply proven by the many in whom the *x*-ray revealed enteroptosis without symptoms and we should carefully discriminate in attributing a functional disturbance of the gastrointestinal tract to an existing ptosis, simply on *x*-ray evidence. The ptosis as such was unproductive of any discomfort whatsoever and all the complicating elements should be alleviated and excluded before deciding upon operative correction. What we needed in the management of these patients was a means of correct classification and for this our present data were insufficient. When such classification was possible, we should be in a position to separate those amenable to medical treatment from those demanding surgical intervention and a comparison of final end results on such a basis only would establish the relative value of our therapeutic measures.

Dr. HENRY A. COTTON of Trenton said that, being connected with a hospital for the insane, he had tried to gather information in regard to the relation of gastrointestinal disorders to mental conditions, inasmuch as he realized that many of these patients were suffering from gastrointestinal disturbances. He presented charts showing the excellent results secured by the method of treatment, which consisted in taking cultures from the tonsils and stomach contents, and if infection with a streptococcus or the colon bacillus was found to be present they treated the patient with lavage

and vaccines made from the organism or organisms found in the culture. Since they had adopted this method of treatment they were discharging fifty patients a month, as against thirty-six during the previous year. He was convinced that many of these insane patients were greatly benefited by treatment directed to the gastrointestinal canal. It had brought about a reduction in the population of the Trenton hospital for the insane such as had not occurred in eighteen years.

Dr. Robert T. Morris was of the opinion that Dr. Cotton was going at this problem in the right way. He said that if there were no brilliant surgical successes in these cases no surgery would be done; but, on the other hand, if the internist always satisfied the patients none would go to the surgeon. If one gave due consideration to the subject of ptosis he would find that most of the "acquired cases" had also stigmata of decline—they belonged to the vagatonics, with stigmata of degeneration, such as a high arched palate, defective ear or scapula, and ptosis was one of the stigmata. Under these circumstances one must remember that function and structure were so closely allied that if there was a variation in structure a corresponding difference in function must be expected. The speaker stated that he had applied all the various forms of treatment that had been described by the different speakers, and he had learned that unless one took into consideration the fact that he was dealing with the stigmata of decline in this class of patients his results might not be satisfactory. There was no doubt that Dr. Goffe's operation was suitable to certain cases, just as other suspensory operations had been successful in certain cases and just as the Wier Mitchell rest cure and other forms of non-operative treatment had been successful in certain cases. The race had gone over the high point of its cultural development and the tendency to decline was now shown in various stigmata; enteroptosis was one of them. In order to make a satisfactory showing for any form of treatment it was essential to have reports on consecutive cases and not only selected cases. Dr. Bassler spoke of depressing surroundings. Now the negative attitude toward life was commonly due to defective structure. Many of these neurasthenics, vagotonics, etc., were persons who had brought upon themselves the very social conditions which were depressing to them. In these patients treatment properly applied to relieve toxic features and peripheral irritations were often effective, and the speaker hoped that Dr. Cotton's report would be given the attention it deserved.

Dr. Fenton B. Turck said that, in speaking of enteroptosis, we must recognize two classes of patients, those who had symptoms and those who had not. In those who had symptoms, the symptoms were not due to displacement, whether the displacement was sidewise or downward, or in whatever direction it might be the symptoms were not the effect of mechanical deviations from the normal position. In searching for the etiology of these displacements we must go back of the mechanical factors. We had in enteroptosis an etiology similar to that seen in acute conditions. For instance, in pneumonia the toxins of that disease frequently produced acute dilatation of the stomach and blood vessels, with collapse and death. In patients having infections in other parts of the body we found the same kind of dilatation of the stomach and intestines, and similar effects resulting from autolyzed tissue toxins from these infections. We had as a consequence a combination of dilatation and atony. Twenty years ago the speaker conducted experiments showing that stasis, atony, and dilatation were the result of autolysis of injured tissue which produced toxins responsible for both acute and chronic conditions. Quite recently he had repeated these experiments. He had taken tissue from an injured animal and transplanted it to another animal with the result that the latter animal became toxic, and if the dose was sufficiently large the animal went into collapse and died. The presence of microbes likewise set up an autolysis of the tissues which gave rise to tissue toxins that produced the phenomena of atony, stasis, and dilatation. In his laboratory experiments on animals he found that the autolyzed products of the tissue walls of the stomach and intestine, when absorbed or intravenously injected, produced atony and dilatation of the stomach and intestines. Why should any one in search for the etiology of these conditions go back to the psychoneuroses when the real cause was a biological one, and one so easily demonstrable? The writer stated that he had published a large number of cases in which he used the colon bacilli in connection with other organisms and made an antigen with human tissue, which, after repeated injections into a horse, furnished a most powerful antigen against the patient's own toxemia. Inasmuch as, according to Dr. Bassler's statement, 50 per cent. of his patients with enteroptosis suffered from intoxication, we must recognize that this was a very important factor in this condition. Another point came up and that was whether in some of the cures attributed to surgery the successful outcome might not be due to an immunity induced by the operation itself. Possibly the operation itself, by injury to the tissue, was instrumental in setting up the process whereby an autovaccine was produced which caused immunity in the subject. In seeking the reason why surgery failed in these cases—for it did fail—such a reason would be found in the fact that the dynamic and mechanical features of the disease which surgery sought to correct were secondary, while the real etiological factors of the disease were to be found in the underlying biological conditions, namely, tissue autolysis caused by microorganisms.

Dr. Bassler, in closing the discussion, said that the failure of surgery, in his observations, had been that the cases were not operated on in the way Dr. Goffe suggested. The operations employed had not cleaned up the abdomen completely whether it was a Coffee operation, a Beyea operation, or a plication of the cecum. When operation was decided upon and carried out there should be a complete job done. A second reason why operative procedures had been failures was that these people who suffered from enteroptosis were characteristically non-adhesion makers. It seems it is the robust and strong type of individual in whom adhesions readily formed; in these thinned-out individuals adhesions were very rare. As to the patients that in his experience were surgical there were first those that did not have the time to go through a course of treatment, and that were still not too young or too old to be suitable for a surgical procedure. He thought it was a mistake to operate on patients in the early twenties or in those who were quite old. Second those cases in which there had been a logical effort made to benefit the patient and no permanent benefit had been obtained. Third, these cases in which we found what he called the diamond-shaped pelvis; almost all of these were surgical cases. Fourth, cases in which there was a marked atony of the stomach and right colon with prolapse of the hepatic flexure; these in great proportions were surgical cases. Fifth, cases in which there was a marked ptosis as well as uterine procidentia; these were almost always surgical cases. This, in his experience was the best reply he could give to Dr. Sturmdorf's request for information.

Dr. Goffe, in closing, asserted that the surgical cases must be selected. Since 1889 he had operated on 17 cases. He did not think any one could accuse him of rash surgery when he had operated on only seventeen cases of this kind in thirty years. These patients with relaxation of the abdominal wall, dilatation of the stomach, and ptosis of the colon could not be braced up with medicinal and mechanical treatment so that the abdominal viscera would perform their functions; operation seemed to be the only course that offered relief. If one could get rid of the toxins he conferred a great benefit on the patient; if he could prepare a vaccine that would make the patient perfectly immune that was a great benefit, but there was always a question as to the length of the immunity. He thought therefore that if one drained the culture tube and kept it drained permanent relief was much more certain. Of these 17 patients four were between the ages of 20 and 30 years; nine between 30 and 40; three between 40 and 50, and one was 59 years of age. Fifteen of these patients made satisfactory recoveries—some of them quite phenomenal—one was unsatisfactory, and one death was the direct result of a complication, modification, or supplementary procedure.

AMERICAN PEDIATRIC SOCIETY.

Thirtieth Annual Meeting Held at Lenox, Mass., May 27, 28, and 29, 1918.

THE PRESIDENT, DR. LINNAEUS EDWIN LAFETRA OF NEW YORK, IN THE CHAIR.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page* 1054.)

Migraine in Childhood.—Dr. WILDER TILESTON of New Haven reported a case of migraine occurring in a boy of six years. He stated that the onset was observed at the age of three years. Phenol was found in the urine in large amounts. Meat, fish, and eggs were eliminated from the diet, and only those vegetables were allowed which contained a small amount of protein. Under this régime the amount of phenol excreted in the urine was greatly diminished and the attacks of migraine gradually became less frequent.

Dr. OSCAR M. SCHLOSS reported a case of migraine occurring in a boy eight years of age. This boy also complained of the classical symptoms of migraine, and had a distinct aura of the Gower type. The urine showed a great deal of phenol and indican constantly. The child was put on an almost protein-free diet, getting only the protein contained in a few vegetables with a low protein content. The child had been under observation for five months, and now was having only about one attack in three weeks. There was still some phenol and indican in the urine, but much less than formerly.

The Energy Metabolism of an Infant with Amaurotic Family Idiocy.—Dr. FRITZ B. TALBOT of Boston read this paper. He stated that the diagnosis of amaurotic family idiocy was made by finding the cherry-red spot on the eye with the ophthalmoscope during life, and by post mortem examination. At the time the metabolism observations were made the child was 2 years and 4 months of age. Its metabolism was obtained in the apparatus of the nutritional laboratory of the Carnegie Institution, under the direction of Dr. G. E. Benedict. The nasal metabolism was very low in comparison with that of a normal infant of the same weight, which obviously was very much younger. The metabolism as compared with that of normal infants of the same age was very low. The basic metabolism of the amaurotic family idiot was 39 calories per kilo body weight. Dr. Talbot also compared the metabolism of this subject with that of a cretin and an infant with congenital absence of the cerebral hemispheres which he had previously reported.

Is the Present Frequency of Acute Otitis Media and the Subsequent Mastoid Operation in Some Measure a Reproach to the Pediatrist?—Dr. THOMAS S. SOUTHWORTH of New York presented this paper, in which he showed that little progress had been made in recent years along preventive or abortive lines, and that no studies had been published by pediatricians in whose practice the majority of such cases originated. The essayist, during the past winter, had had 25 cases of acute otitis media in a service averaging about 80 infants under fifteen months of age. These had been under the close supervision of a visiting otologist who had found in some five of them indications of mastoid involvement, yet all had escaped mastoid operation, and the discharge had ceased under treatment in all of the infants save one, which at the time of writing was nearly well. Combinations of cocaine, adrenalin, carbolic acid, alcohol, and glycerin, designed not only to relieve pain but to reduce engorgement and act antiseptically by absorption or osmosis, had been used from time to time. Should we not again ask ourselves if these posssessed absolutely no efficiency, and whether they could not be made to have abortive power in a certain percentage of cases which might thus be saved paracentesis? The warning against blowing the nose in the recumbent or supine position was of such eminent wisdom that the writer had extended it to routine directions in all cases of acute infectious diseases in which there was danger of middle-ear involvement through the Eustachian tube. They would do well to consider the following questions: 1. Were there any therapeutic measures which tended definitely to prevent middle-ear infections in acute nasopharyngeal conditions? 2. Were there any abortive measures which were reasonably efficient in beginning otitis media? 3. Could not some measures be devised by well directed research? 4. Were we correct in assuming that immediate early paracentesis was always indicated in all cases of effusion into the middle ear? 5. To what degree and under what circumstances, after paracentesis, was the pediatrician justified in counselling delay in the presence of the classical indications for mastoid operation. 6. Was the frequency of acute otitis media and of mastoidectomy inevitable, or was it due to a complacent neglect of further research in this field? The members of this Society, from their wide experience, should contribute something toward the solution of these problems.

Dr. SAMUEL S. ADAMS of Washington said that the otologists objected to the preparations usually put in the ear to allay earache, but he felt that he had allayed earache with a 5 or 10 per cent. solution of carbolic acid and glycerin when there was inflammation of the middle ear, but not bulging. When the membrane was bulging he believed they should call in a skillful otologist.

Dr. GODFREY R. PISEK said he was inclined to be rather conservative in the treatment of middle-ear conditions, but he thought the otologists leaned more to the side of operation.

Dr. FRITZ B. TALBOT of Boston said he thought the problem of prevention lay in the prevention of colds, which were the source of most of our ear troubles. The baby's nose should be wiped, and not blown, and the same was true of older children. As a rule, he was opposed to operations on the ear during the course of the acute infection, though there might be instances in which an operation favorably affected the course of the disease.

Dr. ISAAC ABT of Chicago said the membrane should be punctured only when it was bulging and when there was a reasonable suspicion of pus in the middle ear. So far as the mastoid was concerned, the pathological studies showed that in the exanthemata and grippal diseases there was more or less inflammation of the mastoid and antrum, and many of these cases recovered without operation.

Dr. HERRMAN of New York said he had fewer mastoid operations at present than in former years, and he was inclined to be conservative as regarded operation. It was frequently better to wait a little if one could keep the case under observation. He had seen as many cases of mastoid disease follow incision of the drum as when he had allowed the drum to remain red for some time. It was a mistake to teach that every red drum should be opened. He warned against the snuffing of salt water, which, he stated, was a very dangerous procedure.

Dr. L. EMMETT HOLT said that he thought there was much unnecessary operation on ears and that it was time for the pediatricians to urge a more conservative attitude.

Dr. ROWLAND G. FREEMAN of New York said he believed no one operated on a drum that was not red and bulging, and he could not agree that there was a tendency to operate too frequently.

Dr. HOWARD C. CARPENTER warned against the digital examination of the nasopharynx for adenoids. By putting the fingers into the nasopharynx one might stir up an infection that was inactive. He thought that both sides of the nose should be open while the nose was being blown. He also made a plea for a conservative position as regards mastoid operation.

Dr. HENRY DWIGHT CHAPIN of New York spoke of the difficulty of seeing the drum in young infants. Many children were operated on who would probably get well without operation, but no one seemed to be able to tell in what cases recovery would occur without operation. It seemed to him that in blowing the nose, keeping the mouth open was better than trying to keep one or both nostrils open.

Dr. CHARLES GILMORE KERLEY of New York said that the mastoid operation was not a terrible one and that most cases recovered. It was just as well to open the mastoid and drain posteriorly as to run the risk of getting adhesions and chronic deafness.

Dr. LANGLEY PORTER of San Francisco said that one

way to prevent infection of the nasopharynx in children was to have the nurse or mother wear a respiration veil when she had a cold.

Dr. ALFRED F. HESS of New York said that in an institution where there were 400 children they had had but four cases of mastoiditis in the past five years. The plan they had carried out was to puncture red and bulging ears. He believed that frequently the systemic condition had much to do with the ear condition, and that in considering prophylaxis this should be taken into consideration.

Dr. WILLIAM P. NORTHRUP of New York called attention to the importance of the pediatrician looking out for otitis media during measles. This was a point he should not forget where there was a rise in temperature during measles or pneumonia.

Dr. HERBERT B. WILCOX of New York said that sometimes frequent irrigations so devitalized the drum membrane that the superficial layer was raised like a blister, and in some of those cases it might be necessary merely to incise through the outer layer. One criticism that might be made of the pediatrician was that when he opened a membrane he neglected to take a culture at times, and then when the otologist was called in he had difficulty in interpreting the condition because he did not know what organism was causing it.

Dr. DEWITT H. SHERMAN of Buffalo warned against the use of the two-way tubes for irrigation. In the prevention of otitis media they would have to take into consideration the lack of immunity; that was the predominating influence that determined the extent of the involvement.

The Relative Morbidity of Breast and Bottle Fed Babies.—Dr. H. M. MCCLANAHAN of Omaha presented this communication, which was based on the answers received to a questionnaire sent to prominent pediatricians throughout the country, asking their experience as to the relative susceptibility of breast and bottle-fed infants (*a*) in reference to contagious and infectious diseases, and (*b*) in reference to general infection. They were also asked the relative rate of growth and development (physical and mental) of breast and bottle-fed infants, and a request was made for any literature on the subject. Seventy answers were received to the questionnaire, among which were comprehensive data from Dr. Sedgwick on 700 infants and a table from Dr. Pisek which the writer had permission to use. A summary of this data showed the following: (1) Superiority of breast milk might be due to chemical and biological differences which rendered it more readily usable by the infant. As a result, it had a more natural energy which it could apply to the invading organism. (2) Breast milk might contain natural antibodies or protective ferments, both specific and non-specific. (3) Breast-fed infants were less susceptible to infection, the two exceptions being influenza and tuberculosis. (4) Breast-fed infants resisted infection more quickly and with less injury. (5) Breast-fed infants have less morbidity than properly fed bottle infants; that larger group of badly fed infants had a still greater disadvantage.

The Disadvantages of Low Fat Percentages.—Dr. ALFRED HAND of Phildelphia read this paper. He stated that he looked upon anything less than 2 per cent. as a low fat percentage, from 2 to 3 as moderately low, from 3 to 3.5 as a fair percentage, from 3.5 to 3.8 as normal, and anything above 4 as a high fat percentage in the artificial feeding of infants. For a while past the advantages of low fat feeding had been overemphasized. Because a child's digestion had been upset by a mixture too rich in fats it was hardly necessary to brand that child as having fat intolerance for the rest of this life. If a low fat percentage were given over a long period, the general nutrition of the child would be more or less permanently damaged. The main way in which this damage was brought about was summed up in the one word "rickets." Constipation and failure to gain in weight were the two conditions that might be troublesome with the low fat percentages, and low protein as well, unless the carbohydrates were raised considerably above the amount existing in either human or cow's milk. As a temporary measure this might be of value, but it appeared to the essayist that a more lasting benefit was obtained by raising the fat percentages as rapidly as possible. Several factors that seemed to influence the handling of fat in the dietary were climate and the breed of cows. A child what showed intolerance to fat in the summer would often handle even a higher percentage with ease when cool weather came.

Ascending Infection of the Urinary Tract.—Dr. HENRY F. HELMHOLZ of Evanston, Ill., after reviewing the routes by which infection of the urinary tract might take place reported experiments in a series of rabbits that were infected by the injection of a pure culture of colon bacillus isolated from a spontaneous case of pyelitis in a rabbit. In a series of 32 intracystic injections, 15 of the animals showed a definite pyelitis. Of this entire series of animals only one showed abscesses of the kidney. The presence of pyelitis was controlled both pathologically and histologically. The histology of the ureters and kidneys could be grouped roughly into two groups: (1) Those in which there were definite evidences of ureteral and periureteral infiltration and infiltration of the pelvis and (2) those in which the findings in the kidneys were practically only pus in the pelvis. In the first group there were five instances and in the second ten. In all probability there were two routes by which infection was accomplished, namely, by way of the lymphatics and by direct extension up the lumen of the ureter.

Immunity Reactions in Hydrated and Concentrated Tissue.—Dr. FREDERIC W. SCHULTZ of Minneapolis presented this paper. He stated that it was well recognized that certain types of organisms succumbed more readily to the invasion of disease than others. This had crystallized into the idea that apparently fat plethoric organisms showed on the whole a lesser degree of resistance than the lean and fairly emaciated organism. The work here reported was undertaken to show whether there was any difference in the defensive mechanism of hydrated or concentrated tissue, using determinations of immune reactions as an index. Parallel series of guinea pigs were selected as nearly alike as possible in age and weight. During the preliminary feeding stage, covering a considerable period, the attempt was made in the fat series to cause increase in weight as rapidly as possible through the use of liberal carbohydrate feeding, particularly maltose. The weight increase occurred rapidly if the pigs were kept under good conditions. Some allowance was made for normal growth. The lean series of guinea pigs was kept on a balanced ration just sufficient to sustain them. The weight loss was brought about gradually and amounted to 25 to 35 per cent. of the original body weight. The lysin reaction was then compared in 15 fat and 18 lean animals, the animals being immunized against blood cells by intraperitoneal inoculations. The precipitin reaction was carried out on 11 fat and 11 lean animals. The agglutination was carried out on seven fat and seven lean animals. The tables presented showed that the lysin reaction was negative or nearly so in practically all of the fat animals, but was positive, sometimes to a marked degree in over 60 per cent. of the lean animals. The precipitin reaction was uniformly negative in both the fat and the lean series. For some unaccountable reason the guinea pig serum did not give the precipitin reaction. Far reaching conclusions from a study of this kind were not warranted. If, however, immunity reactions were a good criterion of tissue resistance the rather striking behavior of both lysin and agglutinin reactions would seem to indicate that there was a difference in favor of concentrated tissue and that the theoretical consideration expressed by Czerny and other observers were substantially correct.

A Protective Therapy for Varicella, and a Consideration of Its Pathogenesis.—Dr. ALFRED F. HESS presented his communication, in which he described an attempt at immunization against varicella in 38 children about three or four years of age. These children were vaccinated intravenously according to the technique previously described by the writer. None of these children developed any local or general signs, nor any eruption suggestive of varicella, with the exception of one case, in spite of proximity with the disease. Vaccinations of this kind induced neither local nor general reactions. The acquisition of immunity likewise indicated that the specific virus was contained in the vesicles. The application of the lymph to broken skin or mucous membranes failed to bring about satisfactory immunity, although it also occasioned no disorder. These investi-

gations had a secondary bearing as to the natural portal of entry of the varicella virus into the body. As the skin and mucous membrane could be excluded in this connection, it seemed most probable that the virus entered by way of the respiratory tract, and that contagion came about through the air. This mode of infection would account for the almost unexampled communicability of the disease.

Intrathecal Injections of Horse Serum in the Treatment of Chorea.—Dr. LANGLEY PORTER of San Francisco presented this preliminary study of seven cases of chorea treated by the injection of horse serum. He also reported another case treated by the method Mahrtens of Standford University was using in the treatment of cerebrospinal syphilis, namely, the injection of salvarsan six to twelve hours after the preliminary intrathecal injection of horse serum. The first four patients received an initial injection of 20 c.c. of normal inactivated horse serum, half an hour after a half of c.c. of the serum had been given subcutaneously, in order to test whether the patient was sensitive to the serum. Five of the patients received a second injection on the fourth, fifth, and sixth days following the initial treatment. Two sets of unpleasant reactions had followed the use of the serum within the spinal canal, an immediate reaction evidenced by prostration, headache and sometimes by severe vomiting, and a reaction that appeared after a week and was evidenced by the usual symptoms of serum disease. The most striking results followed the use of the horse serum in maniacal and severe cases. While the number of cases treated was too few to warrant the drawing of definite conclusions, their experience had been such that they felt that they had a right to hope that further investigation would establish the sera as a valuable measure in the treatment of suspected cases of chorea.

Dr. OSCAR M. SCHLOSS of New York related some of the results that they had had on Dr. LaFetra's service at Bellevue Hospital with the method of Goodman. They had tried this treatment in twelve cases and these cases did no better than twelve control cases that did not get the serum. Some chorcics might have become better after the first, second, or third dose of the serum, but one frequently saw the same improvement in children treated by the usual means.

Dr. CHARLES HERRMAN asked whether a certain amount of spinal fluid was removed before the serum was employed and whether it was possible that the improvement was the result of the relief of intraspinal pressure.

Dr. LAFETRA said that it was not altogether a simple matter to draw off the blood, keep it sterile, and then inactivate it according to the method of Dr. Goodman. For some reason they did not get good results with this method, and they did not feel that they were justified in continuing to use it. Dr. LaFetra said he would like to see someone try Dr. Porter's method for he thought there would be advantages in using other than an autogenous serum.

Dr. PORTER said that reference had been made to the fact that the psychical element might be responsible for the favorable outcome of cases under this treatment. In his paper he had called attention to the fact that the psychical disturbances of chorea could never be overlooked, and that it might be that the results which followed the use of the serum were evidence of a successful if unwitting application of suggestive therapy. He thought it was better to withdraw more spinal fluid than the amount injected. All of these cases showed high intraspinal pressure. There was, however, nothing in the spinal fluid to lead one to believe that there was an infection. The cell count and the globulin of the spinal fluid were normal.

A Comparison of the Carbon Dioxide Tension of the Alveolar Air, the Bicarbonate of the Blood Plasma, and the Hydrogen Ion Concentration of the Urine in Infants with Acidosis.—Dr. OSCAR M. SCHLOSS of New York presented this paper, which recorded observations made on cases of acidosis which occurred as a complication of gastroenteric disorders, and were of the type described by Howland and Marriott. He stated that he had attempted to compare the reaction of the urine, the carbon dioxide tension of the alveolar air, and the plasma bicarbonate, with special reference to the diagnosis and treatment of acidosis. He found that the plasma bicarbonate was probably the most accurate index of the alkaline reserve of the blood, and this was used as a standard by which the other methods were compared. The reaction of the urine of infants was more acid than that of adults on a mixed diet, and it was definitely influenced by diet. The fact that the urine of infants was more acid than that of adults was probably due to the fact that the diet of infants was poorer in bases than that of adults. Correspondingly, the carbondioxide of the alveolar air and the plasma bicarbonate were also lower. In acidosis the urine was always very acid, but in moderate degrees of acidosis the urine was no more acid than in some normal infants on an acid-producing diet. Urine with a hydrogen ion concentration of six or less excluded the possibility of acidosis. The carbon dioxide tension of the alveolar air corresponded very closely to the plasma bicarbonate in normal infants and in cases of acidosis before sodium bicarbonate had been administered. In acidosis, after the bicarbonate had been given and the plasma bicarbonate brought to normal, the carbon dioxide of the alveolar air was often much too low. This was probably due to continued irritability of the respiratory center.

Dr. W. M. MCKIM MARRIOTT of St. Louis said that his experience had been practically the same as that of Dr. Schloss, particularly in regard to the failure of the alveolar carbon dioxide to indicate the presence of acidosis after sodium bicarbonate had been administered. In regard to the reaction of the urine, if one took as his guide for treatment the alkaline reaction to litmus he might make a mistake and give too much bicarbonate. Creosol purple was a much more accurate indicator.

Medical Prophylactic Work in the Army and Its Application to the Civil Population.—Dr. PAUL ARMAND-DELILLE of France read a paper on this subject. (See MEDICAL RECORD, June 22, p. 1104.)

Child Welfare Work in France.—Dr. WILLIAM PALMER LUCAS spoke on this subject. (See MEDICAL RECORD, June 22, 1918, p. 1105.)

The Massachusetts Child Conservation Committee. The Details of Organization and Work.—Dr. RICHARD M. SMITH of Boston read this paper, in which he stated that the popularity of child welfare campaigns had led to the formation of many new organizations, and that this had resulted in much overlapping and reduplication of work. In Massachusetts they had worked out a plan whereby they had secured a proper coordination of the lay child welfare organizations and the Health Department. They had a central committee, known as the Child Conservation Committee, which had carried on a campaign through which they had obtained the cooperation of local committees in a scheme whereby the actual child welfare work was done by trained public health nurses. A survey of the children of the State had been made and accurate and complete records were kept and filed with the Department of Health. The officers of the Health Department acted in an advisory capacity to the nurses and organizations that were helping them. Some $50,000 had thus far been appropriated to carry on this work, and they were getting very good results and working harmoniously.

Dr. S. MCC. HAMILL of Philadelphia told what was being done in Pennsylvania in the work of organization for child welfare work, where they had some difficulty in getting the State Health Department to cooperate with the women's committees. They had finally succeeded in getting the women's committees to work in accordance with a plan by which the work was to be carried out under the division of child hygiene of the State Department of Health. The character of the survey now being made was very much like that which had been made in Massachusetts, reports were being presented, and suggestions for new work were being considered.

Dr. FRITZ B. TALBOT explained that the funds that Dr. Smith spoke of as being appropriated were raised by the individual committees throughout the State. He related specific instances showing how the trained public health nurses awakened public opinion on this subject and aroused enthusiasm in the work. The $50,000 represented work that had been done by their committees and by the trained public health nurses.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting Held Wednesday, November 13, 1918.

MAJOR JOHN W. WEST, PRESIDENT, IN THE CHAIR.

THIS meeting was held jointly with the Babies' Welfare Association.

What the American Red Cross Is Doing for the French Children, and Its Application at Home.—Dr. J. H. MASON KNOX of Baltimore, Assistant Director, Children's Bureau, American Red Cross in France, regarded the preservation of the baby as the most important public health proposition at present before the civilized world. The problem deserved the unreserved resources of the State and was entitled to the co-operation of private citizens. Working as a detached agency the Red Cross had been able to bring into harmonious co-operation all organizations having to do with the betterment of child life in France. He regarded the situation in France as critical. While the death rate was not exceedingly high, being in one or two provinces under 10 per cent., the birth rate averaged somewhat less than fifteen per thousand. A slowly falling birth rate before the war had, with the withdrawal of men to military service and women to munition work, become a rapidly falling one. The twofold problem presented in France was that of bringing about an increased birth rate and a lower infant mortality. The low birth rate of France was attributed in part to the inborn desire of the French people to live comfortably. The laws of France requiring equal inheritance among children might also be a factor. Since families were thus so small, it was twice as important to save a French baby as that of any other race. The work of the Children's Bureau in France consisted in (1) meeting immediately pressing conditions, and (2) constructive effort. Under the first were included care of the babies of the soldiers, those of the city population, and the children of the refuge families. In a small village near the German front a large number of children who had been subjected to gas attacks had been placed in large military barracks under the medical care of Dr. Lucas of San Francisco. A hospital for these children was afterward developed. A further work of the Children's Bureau had been the establishment of a chain of rural dispensaries illustrating to the poor people of the small villages the method of caring for children; also the institution of automobile dispensaries with the personnel of a doctor, a nurse, and one or two nurses' aids, which made two visits a week in each town. Where there was need, the nurse or aid would be left in the village. A clinic was held twice a week. Two or four automobiles had thus covered the area of thirty or forty miles in the vicinity of Toul and Nancy. A number of tuberculosis camps were also established. In one vicinity nearly a thousand children had been taken to the seashore for the summer, where they had done wonderfully well. A great difficulty to be confronted was that of returning these children to their families, the adults all being needed for the commercial life of the town. Under the Belgian Commission, with which there had been close association in the work of the Red Cross, Dr. Park of Johns Hopkins had opened a clinic for children. The splendid spirit and character of the Belgian children, in Dr. Knox's opinion, gave much promise for the future of Belgium. The Refugee Bureau co-operated with the French officials in finding homes for the people and supplying them with furniture and other needed articles. Every child under twelve years of age, coming through the convoys of refugees, was examined for the detection of infectious disease or other condition which might prove a menace. Twenty miles from Lyons a large château with 200 acres of ground had been acquired by the Children's Bureau, where convalescent cases were kept until able to go to their destination. The German consulate had been taken over by the bureau and converted into a hospital. Two other buildings in the vicinity of Lyons had also been thus used.

Paris was regarded as the center of activities and there the Children's Bureau had opened twenty dispensaries; always, however, after most careful examination that they did not conflict with French organizations and only with the support and encouragement of the French physicians. The nose and throat work in France was regarded as exceedingly important; the complete removal of tonsils was not there done as often as was thought by some of the American physicians it should be done. A small private hospital had been secured for this work and here perhaps a hundred cases a week had been treated. It was the experience of the bureau to find that many of the children needed food rather than drugs. The principal meal of the day was given at the school and this the bureau had supplemented, that the same amount might be given them as before the war. In one section sweetened bread and chocolate had been supplied, the children being told that the children of America were sharing their bread with the children of France.

While the touch of the bureau with the Army was not intimate, the bureau assumed the care of the orphans supported by the American soldiers. The *Stars and Stripes* had given opportunity for groups of soldiers to be responsible for these children, and the Children's Bureau had supplied the orphans and the care, while the soldiers supplied the money. One service rendered by the bureau was the sending by the nurse of postcards written by the mothers to husbands at the front, saying that they had been assisted by the American Red Cross and would be taken care of. Many evidences had been received that such little service was appreciated.

For the constructive work in France there was said to be, of course, at this time unique opportunity. One form of educational propaganda carried out was by the use of automobiles equipped to present infant welfare and tuberculosis work. Reference was made to the work of the Rockefeller Foundation in connection with tuberculosis. A result of bringing together various agencies was the availability of a personnel always ready for follow-up work after interest had been aroused. Crowds of people attended the exhibits showing the pre- and post-natal care of the baby; illustrating also playground work. In these exhibits the "Punch and Judy" show had been used to much advantage in showing the ignorant mother brought to terms. Dr. Knox thought that in America as well this demonstration might be used in putting over some of the practical truths concerning baby welfare work. In three weeks approximately 140,000 people had visited this exhibit. The great need of trained nurses in France was mentioned. To supply this need short training courses had been given, the French physicians giving lectures and the training being received in the dispensaries, and in institutions where mother and baby were cared for. The promotion of the training of the French nurse was regarded by the speaker as one of the most important phases of constructive work the Children's Bureau had been permitted to do.

Intensive work designed to reach every baby had been organized under the French officials. In this plan a ward was divided into certain sections and in a central office a record was made of every child born in the various divisions and the name given to the organization responsible. The mother was visited and a certain allocation made to her if she could keep the baby with her. If by such plan the death rate could be demonstrated to be lowered the ready co-operation of the French people could be readily obtained.

On the non-medical side of the work reference was made to scholarships which had been established in France. A big national organization in association with the American Red Cross had agreed to select promising children of a family to whom scholarships would be awarded.

In closing Dr. Knox observed that infant welfare, the same the world over, should be taught in the schools. Until this were done the teaching must be carried into the homes, and for this the nurse, as the social visitor, was the instrumentality of choice. The relation of infant mortality to the daily wage was said to be very close. For the sake of the baby there should be willingness to supplement the low wage by some form of allocation. Lantern slide demonstration of the work of the Children's Bureau in France closed the address.

Serum for Sycosis Barbae.—This affection is said to prevail extensively in Germany, and Bruck, of Wassermann reaction fame, has prepared a serum against it.—*La Presse Medicale.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

PENNSYLVANIA BUREAU OF MEDICAL EDUCATION AND LICENSURE.

July 9-11, 1918.

(*Concluded from page* 1014.)

OBSTETRICS AND GYNECOLOGY, PHYSIOLOGICAL CHEMISTRY.

1. Should a woman with a deformed pelvis (early in pregnancy) engage your services, name the three most important methods by which you would aim to secure her a living child? In each instance name the limits of measurement of the conjugata vera.

2. Given a pregnant woman (within the first three months) of doubtful intrauterine or extrauterine location, describe in detail how you would determine the correct diagnosis.

3. During the birth of an infant what dangers threaten it? Name the three most important dangers and discuss their prevention.

4. How would you deduce the presence of uterine cancer: (*a*) early? (*b*) late? Describe carefully the difference. Name the most important method of treatment.

5. Name the distinguishing points of difference between uncomplicated retrodisplacement of the nongravid womb, a small uncomplicated pelvic tumor, and fecal content of the lower bowel.

6. When is the induction of premature labor justifiable? In any three cases in which you would consider the advisability of performing any other operation, explain in detail why you would prefer them to premature labor.

7. If, at the third month, a primipara should engage you to care for her through the period of gestation and labor, give in detail your care of the case, including measurements and tests.

8. What symptoms would lead you to the apprehension of an oncoming attack of eclampsia before the convulsions set in? What measures would you take to prevent the threatened attack?

9. Discuss the thyroid gland from the chemical and therapeutic standpoint.

10. (*a*) What are the most prominent organic constituents of commercial meat extracts? (*b*) What is the nutritional value of such extracts?

ANATOMY AND SURGERY.

1. What are the early symptoms of hip-joint disease? What is the anatomical explanation of each of these symptoms?

2. State the avenues and possible points of metastasis of malignant growth of the breast. Upon what symptoms may an early diagnosis of cancer of the breast be based?

3. State the varieties and causes of hemorrhoids, together with the complicating surgical conditions which may follow their presence. Mention two operations for their cure.

4. Given a severe scalp wound, upon what would you base your opinion as to the safety of immediate closure of the wound?

5. What conditions would demand a circumcision (*a*) in the child? (*b*) in the adult? Describe the operation.

6. State in detail the conditions necessary to be present which would warrant the amputation of an extremity. State the structures severed in an amputation through the middle of the arm.

7. How is Colles' fracture produced? What displacements occur and what is their anatomical explanation? State the method of reduction of the fracture.

8. Describe the principles involved in the Carrel-Dakin treatment of wounds. Give a detailed description of the application of the method. Point out the essential differences between this method and the dichloramine-T method.

9. Detail the possible traumatisms produced in a sprain of the ankle. Outline the principles involved in its treatment and the method of securing the result.

10. State the conditions caused by gonorrhea that may require surgical intervention (*a*) in the male, (*b*) in the female. State what operation would be indicated in each instance.

PRACTICE, MATERIA MEDICA AND THERAPEUTICS, HYGIENE AND PREVENTIVE MEDICINE.

1. Name the principal alkaloids in opium. How would you treat a patient addicted to the use of opium?

2. How would you treat: (*a*) diarrhea of cholera infantum? (*b*) diarrhea of an acute gastro-enteritis? (*c*) diarrhea of tubercular disease of the intestinal canal?

3. What medication might be employed in the treatment of chronic digestive inadequacy? What articles of diet would be indicated and what ones contraindicated, especially where fermentative action is pronounced and symptoms of autointoxication are present?

4. Outline the treatment of (*a*) chorea; (*b*) locomotor ataxia.

5. Name two conditions under which each of the following named remedies might be used and give the rationale of their administration: (*a*) oleum terebinthinae, (*b*) oleum tiglii, (*c*) camphora, (*d*) atropine sulphate, (*e*) argenti nitras.

6. Outline the treatment of pernicious anemia and of simple anemia.

7. Discuss the subject of the treatment of pain as it may present itself in the course of any three diseases of your own selection.

8. Discuss the subject of the prevention and treatment of syphilis.

9. Give the average and the maximum dose of the following named drugs: (*a*) hyoscyamine hydrobromide, (*b*) corrosive mercuric chloride, (*c*) santonin, (*d*) tincture of digitalis, (*e*) tincture of aconite, (*f*) strophanthin, (*g*) fluid extract of ergot, (*h*) caffeine, (*i*) amyl nitrite, (*j*) dilute hydrocyanic acid.

10. Discuss the therapeutic application of sodium bicarbonate, of sodium chloride, and of sodium benzoate.

ANSWERS.

OBSTETRICS AND GYNECOLOGY. PHYSIOLOGICAL CHEMISTRY.

1. In contracted and deformed pelvis, the different methods to be considered in delivery of the child are: (1) Induction of premature labor; (2) Forceps; (3) Version; (4) Craniotomy; (5) Cesarean section, or one of its modifications; (6) Symphyseotomy.

So many things have to be taken into consideration that it is quite impossible to lay down any hard and fast rules to govern every case. The following table (from King) is a safe guide:

WHEN CONJUGATE OF DIAMETER OF BRIM MEASURES	THE MODE OF DELIVERY AT TERM IS:
Between 4 and 3½ inches.	By Forceps.
Between 3½ and 2¾ inches	By Forceps, Version. Symphyseotomy. Cesarean section, or Craniotomy, *pro re nata*.
Between 2¾ and 2 inches.	Cesarean section, if child alive. Craniotomy, if child dead.
At 2 inches or less	Cesarean section always. Craniotomy excluded, whether child dead or alive.

2. "When a woman in the reproductive period, after some irregularity of the menses, such as going over the proper time a few days or having only a small, or even a more profuse flow, complains of cramping pains in the lower abdomen, mostly unilateral, with irregular uterine hemorrhage, the suspicion of ectopic pregnancy is aroused. If, suddenly, an excruciating pelvic pain occurs, with dizziness, faintness, or collapse, the diagnosis is almost certain, and is confirmed by finding an extrauterine tumor or the discharge of a uterine decidua. The direct diagnosis of fluid blood in the peritoneal cavity is seldom easy. A sense of soft resistance is found in the posterior vaginal fornix, but the uterus is not displaced. Puncture of the fornix with a long

sharp needle may reveal the blood, but it usually is not necessary for the diagnosis. After twenty-four hours to forty-eight hours the blood-clots become readily palpable and now displace the uterus—that is, a hematocele forms. When the discharge of blood is slower, a peritubal hematocele forms, which increases from day to day, and one can trace the advance of the progress with the finger by successive examinations. The hematocele may be retrouterine, before the uterus, at the side, before or behind, and the organs are displaced in typical directions. A broad-ligament hematoma can more easily be diagnosed from the stormy beginning and the firm, tender tumor at the side of the uterus, displacing it to the side and upward. In all cases where the history of the patient gives only a hint of the possibility of an extrauterine gestation, the examination must be conducted with the utmost gentleness to avoid rupturing the sac. . . . In the early months confusion is often caused by a long cervix softened at its upper part, which allows the fundus to bend backward or to the side. The cervix is hard, is held to be the uterus, and the fundus is thought to be the ectopic sac. By straightening out the uterus the diagnosis may be made certain, but before attempting to do so the presence of an eccyesis must be ruled out. Or the pregnancy is situated in one horn of the uterus and distends this side, the rest remaining hard. This is an 'angular pregnancy,' and is not seldom the cause of error.

INTRAUTERINE ANGULAR PREGNANCY.	EXTRAUTERINE PREGNANCY.
1. History is that of normal pregnancy, though, not seldom occasional slight hemorrhages and pains are present.	1. History of colicky pains and peritoneal irritation for several weeks; then a stormy event (rupture) with severe pain, shock, etc.
2. No expulsion of membrane, unless abortion.	2. Expulsion of decidua.
3. No anemia.	3. More or less anemia.
4. Demonstration of tube and round ligament on outside of the tumor.	4. Tube and round ligament not palpable, or medial to the tumor.
5. Can feel the wall of the uterus pass over onto tumor, especially during a contraction.	5. The mass is separated from the uterus by a groove. This is especially deep in pregnancy in an accessory horn.
6. The tumor is soft, feels like a pregnancy, is high up in the side of the pelvis, and movable as a part of the uterus.	6. The tumor is harder, lies at the side of the uterus or in the cul-de-sac, and is not movable.
7. The angular portion of the uterus contracts.	7. No contractions of the sac.
8. Gradually the typical shape of the uterus returns.	8. The tumor becomes more and more asymmetric at successive examinations.

"Angular pregnancy cannot be differentiated from interstitial pregnancy except by the clinical course. It is well, therefore, to place the patient in a hospital for observation." (From De Lee's *Obstetrics.*)

3. *Dangers which threaten an infant during birth:* Deformity of the head; caput succedaneum; cephalhematoma; fracture of bones; rupture of intracranial blood vessels; injuries to the brain; hematoma of sternomastoid muscle; paralysis (central or peripheral); meningeal apoplexy; asphyxia; atelectasis; infection of eyes.

Prevention of three important dangers: (1) *Ophthalmia.* Take all antiseptic and aseptic precautions, and in every case wash the eyelids of the new-born child with clean warm water, and drop on the cornea of each eye one drop of a 1 or 2 per cent. solution of nitrate of silver, immediately after birth.

(2) *Asphyxia.* Tedious labors should be accelerated, and prolonged pressure upon the fetus (chiefly the head) should be prevented; pressure upon the cord must also be prevented; prolapse of the cord, and winding of the cord around the neck must be looked for, and (if possible) corrected; the air passages must be cleansed as soon as the head is born.

(3) *Paralysis.* Prolonged pressure on the fetal head must be avoided; care must be exercised in the use of forceps; and undue delay in the use of forceps should be avoided.

4. The presence of *early* uterine cancer may be deduced from the presence of an irregular uterine hemorrhage, an offensive discharge from the vagina, and sometimes pain in the pelvis. A microscopic examination may aid in the diagnosis.

Later, the tumor is noticeable, and the patient shows the characteristic cachexia; the uterus may be curetted, and the scrapings examined microscopically. Metastatic growths may be noticed in the pelvis. The growth (if on the cervix) is friable.

Treatment, to be of any value, depends on an early diagnosis. If the cancer is diagnosed quite early, before cachexia and metastasis are present, and before any other structures are involved, complete hysterectomy may prolong the patient's life.

5. In all three of these conditions a mass (or tumor) will be felt in the posterior vaginal fornix, but on bimanual examination, the fundus of the uterus will be absent from its proper position, and the cervix will point toward the vaginal outlet in case of *uncomplicated retrodisplacement. Fecal accumulations* may be removed by the use of cathartics and enemata. In the case of *uncomplicated* pelvic tumor, the mass may be separated from the uterus, and it will be found to differ from the uterus in size, location, and consistency; further the judicious use of the sound will help to differentiate this from the uterus.

6. Conditions that justify the induction of premature labor: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of a fetus toward the end of pregnancy; (6) hydatidiform mole; (7) habitually large fetal head.

And see Question 1.

Cesarean section is recommended in the following cases: (1) Extreme deformity of the pelvis, in which delivery by forceps and version is excluded, and in which craniotomy is either impossible or would be more dangerous to the mother than cutting into the abdomen and uterus; and in which there is not room for a successful symphyseotomy. Such cases present the "*positive*" indication for cesarean section; there is nothing else to be done. Flat pelves having a conjugata vera of 2¼ inches or less, and justo-minor pelves with a conjugata vera of 2½ inches or less, present this positive indication; (2) recently the operation has been done in eclampsia cases, where more conservative methods of rapid delivery were impracticable; and (3) in placenta prævia, chiefly with a view to lessen the infant mortality attending the usual treatment of this complication.

7. A primipara should be instructed fully in the hygiene of pregnancy, by which is meant the care which should be observed by the pregnant woman for the preservation of health and strength both of herself and of the fetus. The pregnant woman should take moderate exercise in the open air; in the last month massage may take the place of exercise. Daily bathing in tepid water, care of the teeth, regularity of the bowels, ample sleep in a well-ventilated room, plenty (but not too much) of simple, nourishing and easily digested food, at regular hours, clothing not too tight, especially about the abdomen and breast; attention to the nipples, regular examination of the urine, and the restriction of marital relations are the main points to which advice should be directed. In addition certain measurements are necessary; a pelvimeter will be required to make these measurements. The interspinal and intercristal diameters are measured, also the distance between the ischial tuberosities and the anteroposterior diameter, as well as the external conjugate. It is well to notice if the subpubic arch is narrowed; the diagonal conjugate is also estimated; from the latter the true conjugate can be obtained.

8. *Symptoms of impending eclampsia:* Headache, nausea, vomiting, pain over stomach, vertigo, ringing in ears, flashes of light, blindness, mental disturbances. *Preventive treatment:* (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action

of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic product and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ.

9. THYROID GLAND. *Chemistry.* "Fresh thyroid extract is alkaline, but if the extract is obtained some time after death it is acid, due to the presence of sarcolactic acid. Thyroid substance contains water, 82 per cent.; solids, 18 per cent. The solids consist of nucleoprotein and iodothyrin (thyroiodine). The latter substance constitutes about 10 per cent., and contains the elements C, H, O, N, P, and I. The iodothyrin is contained in the colloidal substance, which is derived from the granules in the cubical cells lining the thyroid vesicles."—(Lyle's *Physiology.*)

Therapeutics. It is used: (1) *In Myxedema and Cretinism.* In these conditions the effects are most striking. In myxedema the mentality and the physical characteristics are restored; in cretinism the patient may be changed from a maldeveloped and hopelessly idiotic child to a well-developed and more intelligent one.

(2) *After thyroidectomy*—to prevent the usual train of symptoms. It is effective if the parathyroids have not been removed.

(3) *In hypothyroidism*, as after some partial thyroidectomies, and in the late stages of exophthalmic goiter where reversion to colloid has taken place. It is believed that there are many cases of hypothyroidism, with ill-defined symptoms, in which thyroid may be of benefit; but the distinguishing features of this condition have not been satisfactorily determined.

(4) *In Colloid Goiter.* (5) *In Obesity.* (6) *In Rheumatoid Arthritis.* (7) *In Infantile Wasting.* (8) *In Osteomalacia, Rickets, and Delayed Union of Fractures.*

It is contraindicated in the hyperplasia stage of exophthalmic goiter, as it increases the symptoms.—(Bastedo's *Materia Medica, etc.*)

10. *Meat extracts* in themselves have very little food value. They contain a trace of protein and gelatin, but the peculiar value of meat extract lies in the presence of the so-called nitrogenous extractives, namely: creatine, xanthine, hypoxanthine, adenine, guanine, etc. These substances are likewise stimulants. They also call forth a copious secretion of gastric juice, and for this reason have been called secretogogues.—(From *Reference Handbook of the Medical Sciences.*)

ANATOMY AND SURGERY.

1. *The early symptoms in hip joint disease* are: (1) *Pain*, which is referred to the knee, due to the distribution of the obturator nerve to both hip and knee joints. (2) *Flexion of the limb*, with *abduction* and *eversion*, because in this position the capsule of the joint is most relaxed and there is more room for the fluid, and this position affords most comfort to the patient. In *abduction* the upper part of the capsule and the outer part of the Y-ligament are chiefly relaxed; in *eversion*, the inner part of the Y-ligament is chiefly relaxed. (3) *Apparent lengthening of the limb*, due to a tilting down of the pelvis to counteract the shortening produced by flexion and abduction. (4) *Flattening of the buttock and loss of the gluteal fold*, due to flexion of the hip; later on the gluteal muscles may atrophy. (5) *Lordosis*, due to the forward movement of the vertebræ to minimize the inconvenience of the flexed hip.

2. *Malignant growths of the breast* may spread (1) to the axillary glands, (2) the subclavian glands, (3) the retrosternal glands and the mediastinum, (4) and also to the other breast. "A cancerous breast is coextensive with the lymphatics which drain it."

An *early diagnosis of cancer of the breast* is made on the presence of a "lump" in the breast which is at first somewhat moveable but later there is adhesion of the gland to the pectoralis major, puckering of the skin, retracted nipple (if the tumor is in the part immediately below the nipple).

In *doubtful cases* it is well to imagine the growth to be malignant until it is proved otherwise. If the breast is removed, and the tumor is proved benign, the woman has lost a breast; whereas, if it is not removed, and should prove to be malignant, she will lose her life. The best plan is (with the consent of the patient) to prepare for a radical operation, excise a piece of the tumor, have it examined microscopically, and if it proves to be benign, remove the tumor; if it is malignant, remove the whole breast and neighboring lymphatic glands.

3. *Hemorrhoids. Varieties:* External and internal. *Causes:* Dilatation of the hemorrhoidal veins, pressure of the blood in the portal system, absence of valves in the portal veins, constipation, pregnancy, stricture of the rectum, cirrhosis of the liver, and the anastomosis between the portal and systemic veins which occurs between the hemorrhoidal veins. *Two operations for their cure:* (1) Clamp and cautery, (2) Whitehead's operation (removal of the whole pile-bearing area of mucous membrane). *Complications:* Fissure in ano, prolapse of rectum, strangulation of piles, inflammation of piles with thrombosis.

4. In a severe scalp wound, the surgeon should not immediately close the wound if there are any signs of sepsis, or fracture of the skull.

Symptoms of fracture of base of skull: Hemorrhage (from nose, into orbit, from ear, or into tissues), escape of cerebrospinal fluid from nose or ear; concussion or laceration of brain, with coma; various nerve lesions (blindness, ocular paralysis, facial paralysis, deafness).

In a *simple depressed fracture* there is usually some concussion, which is followed by compression from hemorrhage in the neighborhood. The depressed bone also causes compression later by the *spreading edema* it sets up in the brain. If the depression is over the motor area convulsions or paralysis are quickly induced.

In a *compound depressed fracture* the blood escapes and does not produce compression. Concussion may or may not be present. The advent of sepsis produces inflammation of the bone, membranes, and brain, which may be limited if the drainage is free; but if not death soon follows from compression by the inflammatory exudation.

5. *Circumcision is indicated, in children,* in congenital phimosis when accompanied by hydrocele or hernia, balanitis, preputial calculi, ballooning of the prepuce in voiding urine, and certain reflex symptoms such as dysuria, epilepsy, convulsions due to phimosis. *In adults* the operation is indicated for the same set of troubles as in children, and for phimosis dependent upon inflammation, excited by venereal sores, gonorrhea, etc., as well as for simply redundant prepuce without phimosis, when there are any local irritative or reflex symptoms, as spermatorrhea.—(From *Reference Handbook of the Medical Sciences.*)

"*Circumcision* is performed by drawing the prepuce forward and then enclosing it in a pair of clamp-forceps placed obliquely just in front of the glans. The prepuce is next divided with a straight bistoury, and the forceps removed, when the skin and mucous membrane retract. The mucous membrane, if adherent, is dissected loose from the glans; if redundant, it is trimmed with scissors to make it correspond to the line of skin incision; the cut edge of the mucous membrane is next fastened to the cut edge of the skin by a few sutures of silk or catgut."—(Wharton's *Minor Surgery.*)

6. *The indications for amputation* are (1) to save life, *e.g.* in extensive crushes, virulent infections, gangrene, septic diseases of bone, tumors, and aneurysms; and (2) to provide for the fitting of useful artificial sunports when the limb is functionless from disease or deformity. To amputate or not to amputate is a question which often taxes the surgeon's judgment to the utmost, as absolute rules cannot be formulated. The age and general condition of the patient may be such as to necessitate amputation, which under other circumstances would be inadvisable. Furthermore, a laborer who must support a large family can often be more quickly and better prepared to meet life's responsibilities with an artificial limb than with a badly crippled extremity, which to his more fortunate brother is an inconvenience only. In injuries the principal questions to be answered are: (1) Will the blood supply be adequate to prevent gangrene; (2) is the injury to the nerves and muscles so great that a useful limb cannot be obtained; (3) Can infection be prevented or kept under control? 1. Laceration of the main artery or bone alone is not an imperative indication for amputation, as either may be sutured or even tied without

gangrene following, providing the collateral vessels are intact. If both artery and vein require ligation, however, amputation must be performed, unless the injury, a gunshot wound, for example, has not compromised the collateral circulation. Moszkowitz tests the efficiency of the circulation by elevating the limb, applying a tourniquet, then lowering the limb, and after five minutes removing the constrictor. If the circulation is active, the whole limb becomes hyperemic in a few seconds. Parts which remain anemic are devitalized, those which improve in color very slowly will probably become gangrenous. Matas, in order to ascertain the condition of the collateral circulation, maintains the pressure on the artery after removing the tourniquet. 2. Nerves and muscles may be sutured in suitable cases, but they are often so extensively damaged that they either cannot be approximated or repair cannot be expected. Extensive loss of skin in itself is rarely an indication for amputation. 3. Infection is practically never an indication for *primary amputation;* a finger may, however, be amputated immediately after a bite by a venomous snake or after a known infection with very virulent organisms. Unless amputation is positively demanded, *e.g.* in pulpification of the whole limb or a segment thereof, or in cases in which the main artery and vein are destroyed, one is always justified in making an effort to preserve the part by careful disinfection and free drainage. If gangrene or extensive cellulitis follow within a few days, the limb may then be removed (*intermediate amputation*). *Secondary amputation, i. e.* after a number of days, may be required for secondary hemorrhage, osteomyelitis, chronic sepsis, exhaustion, or amyloid disease, or to remove a useless limb after healing has occurred.—(Stewart's *Surgery.*)

The *structures severed in an amputation through the middle of the arm* are: Skin, fascia; *muscles,* biceps, triceps, coracobrachialis, and brachialis anticus; *vessels,* brachial artery and venæ comites, superior and inferior profunda vessels, basilic and cephalic veins; *nerves,* median, ulnar, musculospiral, internal cutaneous, and musculocutaneous; *bone,* humerus.

7. *Colles' fracture* is a transverse fracture at lower end of radius; it is due to falls on the outstretched palm. The line of fracture is about an inch above the wrist, and runs obliquely downward from behind. The lower fragment is driven backward and upward, and rotated to the radial side, carrying the hand with it into the position of abduction and leaving the tip of the radius at the same level as, or higher than, the tip of the styloid process of the ulna. The internal lateral ligament of the wrist is ruptured or the styloid process torn off. The fracture is usually impacted, the upper fragment being driven into the lower. The deformity is characteristic, *viz.:* (1) The hand is abducted; (2) the styloid process is on the same level as, or lower than, the tip of the radius; (3) the upper end of the lower fragment projects above the back of the wrist; on the front is a corresponding depression, while above it the upper fragment projects forward. Union occurs readily, but it is common to get deformity and adhesions about the site of fracture. *Treatment:* Disimpaction and reduction are brought about by grasping the hand by the "shaking hands" grip, extending and adducting the hand and lower fragment. The arm is then fixed on a splint. It is very important in this fracture to start massage and passive movement not later than the end of the first week, to prevent stiffness. Union is firm in three weeks.—(*Aids to Surgery.*)

8. *Carrel-Dakin treatment of wounds.* "The instillation method of sterilization, commonly called the method of Carrel and Dakin, introduces into every part of an infected wound a continuous amount of an antiseptic fluid, not for irrigation, but for aseptization. Sodium hypochlorite 0.5 per cent. solution is used. The wound is first cleansed under strict aseptic precautions; all foreign matter is removed. The skin is sterilized with iodine. Necrotic tissue is cut away. Hemostasis is secured. Counter openings are rarely needed, and when made they are not placed at the dependent parts, as the object of the treatment is to cause the retention of the antiseptic fluid. For superficial wounds several layers of gauze are placed over the wound and a circular rubber tube perforated with many holes is placed on the gauze. As applied in France the method consisted in wrapping the ends of the tubes in Turkish toweling, and laying the tubes on the wound surface. For deeper wounds a tube is passed to the depths of the wound. If the wound is a penetrating one, an unfenestrated tube should reach the bottom of the wound, and the fluid allowed to return around the outer sides of the tube. If the wound passes all the way through a part or has an opening at the bottom, the tube should be passed into the dependent opening to the top of the wound. The fluid then flows back along the tube. The upper opening should be plugged with a tampon of gauze to cause the retention of the fluid. Deep wounds may be dressed in such a way that the tubes pass through the dressings. It is always best that the tubes enter closed cavities which will retain the instilled fluid. Discharge of pus need not be provided for, because when properly carried out this treatment prevents suppurative discharge. Wounds which are widely open should be immersed every two hours for ten or fifteen minutes in the hypochlorite solution. The skin may be protected from irritation by covering it with sterile petrolatum. In wounds which require dressing, the surrounding skin should be covered with gauze saturated with petrolatum. In compound fractures the same principles apply. In large wounds with multiple passages and excavations, a tube should pass into every crevice and cavity. Each tributary tube should have its extreme end closed by tying it about with a ligature. The tubes should have many perforations. All of these tubes should be connected with the common tube coming from the irrigating reservoir. For this purpose a Y-glass tube may be used or a glass tube with multiple nipples for attachment. The tubes are left constantly in place. The fluid is allowed to flow into the wound every two hours by releasing the shutoff. The flow should be enough to bathe all of the wound but not enough to cause much overflow. The flow may be allowed to be free enough once a day to constitute an irrigation. Every second day a drop of secretion should be taken from the wound, and the number of bacteria in a given amount recorded. When bacteria have been absent for three days the wound may be regarded as sterile. It is customary in some hospitals to take a loop full of secretion from the wound once a day; when only one bacterium is found after examining twenty loopfuls, the wound may be sutured and healing expected. By this treatment wounds of the soft parts are usually rendered approximately sterile in from five to ten days. Wounds with necrotic tissue require longer. Compound fractures require from two to five weeks. Secondary sutures may always be applied when the wound has been found free of bacteria. This bacterial control is a highly important feature of the technique."—(Warbasse's *Surgical Treatment.*)

"The *dichloramine-T method* is an outgrowth of experience with the first Dakin solution of the hypochlorite of soda. Dakin has substituted the dichloramine salt, twice as rich in chlorine, for the chloramine-T which he first used. This new preparation in some important respects seems to be better than the first hypochlorite of soda. It is, however, only a change in one portion of Carrel's method. The rest of Carrel's technique, the wide excision of all damaged tissue, the later substitution of the paste dressing, the constant bacteriologic testing of the degree of sterilization are quite as important as the particular chlorine salt employed."—(Keen's *Treatment of War Wounds.*)

9. The *possible traumatisms in a sprain of the ankle* are: Rupture of one or more ligaments, bruising of the synovial membrane, loosening a separation of cartilages, hemorrhage into the joint and surrounding tissues, laceration or displacement or stretching of muscles and tendons, injury to vessels and nerves, contusion of the skin, and sometimes separation of a piece of bone or cartilage.

Treatment: "Sprains are best treated by early massage and movement, combined with firm, elastic pressure. In the ankle, for example, massage should be commenced at once, the part being gently stroked upward. The process is painful for the first few minutes, but soon ceases to be so and becomes soothing. The rubbing is continued for from fifteen to twenty minutes, the patient being encouraged to move the toes and ankle. A moderately firm elastic bandage or strips of adhesive plaster are then applied, care being taken not

to constrict the limb and so interfere with the circulation. The massage is repeated once or twice a day, the sittings lasting for about half an hour. The patient should be encouraged to move the joint from the first, beginning with the movements that put least strain upon the damaged ligaments, and gradually increasing the range. In the course of a few days he is encouraged to walk, or otherwise to use the joint without subjecting it to strain. Alternate hot and cold douching, or hot-air baths, followed by massage, are also useful. Complete rest and prolonged immobilization are to be condemned."—(Thomson and Miles' *Surgery.*)

10. In the *male*, gonorrhea may cause: Buboes (treated by incision), abscesses (treated by incision), balanitis (if complicated by phimosis, the foreskin must be slit up, or circumcision performed), suppuration of Cowper's glands (incision is indicated), stricture (treated by dilatation), retention of urine (treated by catheterization), prostatitis and vesiculitis (may require incision). In the *female*, abscesses (need incision), pyosalpinx (treated by removal of the infected tube), ovaritis (may need removal of ovary), peritonitis, and adhesions.

PRACTICE, MATERIA MEDICA AND THERAPEUTICS, HYGIENE AND PREVENTIVE MEDICINE.

1. The *principal alkaloids of opium* are: Morphine, codeine, thebaine, narcotine, narceine, papaverine.

Treatment of a patient addicted to the use of opium is thus summed up by Bastedo (*Materia Medica*, etc.): (1) Isolation from friends and hirelings. (2) Gradual withdrawal of the drug in from two or three days to a week. Accompanying the withdrawal there may be diarrhea, cramps in abdomen, back, and legs, intense restlessness, and mental and physical suffering. (3) The substitution for a time of other drugs, of which great favorites are atropine and hyoscine. Keeping the patient in a state of partial narcosis for several days tends to prevent the discomforts which cause the craving for morphine. (4) Nourishing food, to the extent of overfeeding. (5) Massage, baths, and general measures to improve the hygienic conditions of living.

2. The *diarrhea of cholera infantum* is treated by the administration of castor oil or calomel, followed by lavage and intestinal irrigation; afterward, a sedative astringent, such as bismuth subnitrate or chalk, may be administered. The child must not receive any milk during the first few days, but must be nourished with barley water, plain boiled water and fresh beef juice.

The *diarrhea of acute gastroenteritis* is treated by castor oil or magnesium sulphate, followed by opium.

The *diarrhea of tuberculous disease of the intestinal canal* is treated by administration of bismuth subnitrate, and an antiseptic such as guaiacol carbonate; sometimes lead acetate or nitrate of silver may be of more benefit.

3. *Treatment of chronic indigestion:* "The medicinal treatment should be based upon the state of the gastric secretion. In conditions of subacidity, dilute hydrochloric acid (15 minims), in a glassful of water, should be given with each meal. In many cases, however, instead of supplying the deficient hydrochloric acid, we can stimulate the secretion and improve the motor power of the stomach with tincture of nux vomica, beginning with 15 minims three times a day and gradually increasing the dose to 60 minims or more. The bitter tonics, gentian, cinchona, quassia, calumba, condurango, cardamoms, etc., are extensively used and are of value in improving the appetite and stimulating the secretion and motor power of the stomach. Digestive ferments (pepsin, pancreatic preparations, etc.) may be of service in supplying a deficient digestive ferment pending the restoration of the gastric functions, but they are less important than was formerly believed, the hydrochloric acid being the more important factor and activating the zymogens already present. In protracted cases silver nitrate, ⅛ grain combined with extract of belladonna or hyoscyamus, ⅛ grain three times daily, if there is much pain and hyperacidity, is of value.

"Tea, coffee, alcohol, tobacco, pastry, hot bread, hot cakes, fats, sweets, pork, veal, etc., must be prohibited. In some cases mere regulation of the diet suffices to dissipate all the symptoms. In other cases a strict dietetic regimen is imperative, for a time at least; in some cases, especially those occurring in liver cirrhosis, Bright's disease, etc., a milk diet for several weeks may be tried. The milk should be given in stated amounts at regular intervals and about 2 liters in the twenty-four hours. It may be diluted with Vichy or lime water, or, especially in the event of nausea, sodium bicarbonate (5 to 10 grains) may be added to each glassful. For a short time the milk may be peptonized, or buttermilk may be substituted. In most cases it is unnecessary to restrict the diet to milk; most patients can digest, in addition to milk, dry toast, chicken, and roasted or broiled red meats. Farinaceous foods, especially potatoes and coarse vegetables, are a fruitful source of trouble and must be interdicted, especially in the event of flatulence or acid eructations. As the patient improves, the diet may be made more liberal by the addition of eggs, broths, and rice; and green vegetables, such as spinach, lettuce, fruits, etc., may be allowed; but pastry, fried foods, coarse vegetables, strong condiments, and meats, such as pork and veal, must be prohibited."—(From Kelly's *Practice of Medicine.*)

4. *Treatment of chorea.* "Rest of body and mind is an essential element of the treatment. The child should be taken from school and placed under the most favorable hygienic conditions. Amusement in the open air when the weather is fine is to be recommended. As the child is usually anemic, iron is indicated in the majority of cases. Among the special remedies arsenic holds the first place. Fowler's solution may be given in doses of two drops thrice daily, gradually increased to eight or ten drops thrice daily. If arsenic fails, cimicifuga should be tried. A dose of 10 minims of the fluidextract may be given after meals and gradually increased to ½ fluidram or more. Salicyl compounds and antipyrin are sometimes useful. If the movements are very violent and interfere with sleep, recourse must be had to chloral, bromides, trional, or hyoscine."—(Stevens' *Practice.*)

Treatment of Locomotor ataxia. "Rest is an important factor in the treatment. Erb advises that the patient should live as if he were an old man, quietly, regularly, and with no excitement. Mental fatigue should also be avoided. Sexual excesses are exceedingly injurious. The diet should be nutritious and easily digestible. Alcohol and tobacco should be used sparingly, if at all. Flannel should always be worn next to the skin. Massage affords a valuable means of securing the benefits of exercise without the expenditure of energy. Systematic reeducation of coordinating movements, as originally recommended by Frenkel, has been found the most effective remedy for the ataxia. Even in advanced cases, in which there is marked disturbance of sensation, this method of treatment is not without benefit, and the improvement may last for years if the disease is stationary or only slowly progressive. Tepid baths of 80°-85° F. are sometimes of distinct service. They should be suspended, however, while the exercise treatment is being used. Salvarsan, mercury, and iodides should be given a thorough trial in all cases in which syphilis is suspected."—(Stevens' *Practice.*)

5. *Oleum terebinthinæ* may be used (1) in case of tapeworm, as an anthelmintic and teniacide; (2) in case of muscular rheumatism, as a counterirritant.

Oleum tiglii may be used (1) in case of apoplexy, as a cathartic; (2) in a liniment in case of chronic bronchitis, as a counterirritant.

Camphora may be used (1) in a liniment in case of sprains, as a rubefacient; (2) in whooping cough, as an antispasmodic.

Atropinæ sulphas may be used (1) to facilitate ophthalmoscopic examination, as a mydriatic; (2) to check the night sweats of phthisis, as an anhidrotic.

Argenti nitras may be used (1) in ophthalmia neonatorum, as a germicide and antiseptic; (2) on ulcers, as a stimulant.

6. *Treatment of pernicious anemia:* "Fresh air, rest, and a diet as liberal as the digestive powers of the patient will permit are requisite. Warm salt baths and massage are valuable adjuvants to internal treatment. The teeth should receive careful attention. If there be gingivitis or pyorrhœa alveolaris, antiseptic mouthwashes should be used at frequent intervals. Arsenic

is the most valuable drug. It may be given in the form of Fowler's solution, the dose being gradually increased from 2 or 3 to 15 or 20 minims three times a day. Iron is rarely of service. Bone-marrow is sometimes efficacious. Inhalations of oxygen have been recommended. Appropriate anthelmintic remedies should be given, of course, in the cases in which intestinal parasites are present. Digestive disturbances are often benefited by the administration of diluted hydrochloric acid and a bitter."—(Stevens' *Practice.*)

Treatment of simple anemia (chlorosis): "Fresh air, sunlight, open-air exercise, and nourishing food are valuable aids in treatment. Very severe cases require complete rest in bed. If there be a good reaction, warm baths, followed by short cold douches, are efficacious. Iron is almost a specific. It is most frequently prescribed in the form of Blaud's pills, of which the dose is three pills, gradually increased to nine, a day. Laxatives, preferably mild salines, rank next in importance to iron. Arsenic is distinctly less valuable than iron. Superacidity of the gastric juice is best treated by alkalies."—(Stevens' *Practice.*)

7. *Pain* in *locomotor ataxia* may be treated by antisyphilitics, antipyrin, acetyl salicylic acid, or morphine.

Pain in *mucous colitis* may be treated by codeine, heroine, belladonna, or (as a last resource) morphine; morphine should be avoided if possible, because it is constipating.

Pain in *gastric cancer* may be treated by opiates given by the mouth, by rectal suppositories, or by hypodermic injection.

8. *Prevention of syphilis* may be brought about by (1) scientific and practical control of prostitution (this is always opposed); (2) the education of the public on the dangers of venereal diseases (this is generally opposed); (3) adequate instruction in sexual hygiene; (4) the use of a protective, such as calomel ointment, before and after sexual connection.

Treatment of syphilis: Intravenous or intramuscular injection of salvarsan in dose of 0.5 gram, to be repeated twice at intervals of a fortnight. Intramuscular injection of calomel or administration of mercury with chalk by mouth. Iodide of sodium or potassium must also be administered during the second year. This may be combined with the mercury by the administration of the protiodide of mercury. Sometimes mercury may be given by inunction. The patient must have his teeth attended to, use a mild antiseptic mouth-wash, and should give up alcohol and tobacco. Calomel or iodoform may be used as a dusting powder for the chancre.

9. *Hyoscyamine hydrobromide*, average dose 1/200 grain; maximum dose 1/120 grain. *Corrosive mercuric chloride*, average dose 1/20 grain; maximum dose 1/10 grain. *Santonin*, average dose 1 grain; maximum dose 5 grains. *Tincture of digitalis*, average dose 8 minims; maximum dose 20 minims. *Tincture of aconite*, average dose 5 minims; maximum dose 15 minims. *Strophanthin*, average dose 1/60 grain; maximum dose 1/50 grain. *Fluidextract of ergot*, average dose 30 minims; maximum dose 60 minims. *Caffeine*, average dose 2½ grains; maximum dose, 5 grains. *Amyl nitrite*, average dose, 3 minims; maximum dose 5 minims. *Dilute hydrocyanic acid*, average dose 1½ minims; maximum dose 3 minims.

10. *Therapeutic uses of sodium bicarbonate:* "In solution or powder in burns, acute tonsilitis, and poisoning by Rhus toxicodendron; also to relieve itching. Internally, much employed in dyspeptic conditions, especially hyperacidity of the stomach, and in the acid diarrhea of infants. The effervescence resulting from the successive employment of sodium bicarbonate and tartaric acid has been made use of in the stomach to excite emesis in cases of narcotic stupor and in the intestine to overcome intussusception. Good results have been reported from large doses of sodium bicarbonate and carbonate in diabetic coma."

Therapeutic uses of sodium chloride: "Locally, it is of service in affections of the mucous membranes, and salt baths are invigorating as well as cleansing. A strong solution constitutes one of the best injections for threadworms, and salt solutions are also used to limit the action of silver nitrate. Hot salt, enclosed in bags, is a good application in lumbago and various other painful conditions. Internally, as an emetic and also in dyspeptic conditions, administered in carbon dioxide water or in the form of natural mineral waters. Solutions of salt in distilled water are given by intravenous injection or hypodermatoclysis in conditions where the body has lost much fluid, and also in carbon dioxide or coal-gas poisoning and in uremia and similar intoxications. In poisoning by silver nitrate sodium chloride arrests the corrosive action."

Therapeutic uses of sodium benzoate: "Locally, wounds, ulcers, sinuses, etc.; chilblains; the itching of urticaria or eczema; chapped lips, hands, or nipples; catarrhal affections of the pharynx or larynx. Internally, disordered conditions of the urine (as ammoniacal urine and phosphaturia); vesical calculi; chronic gonorrhea; incontinence due to alkalinity of the urine; chronic Bright's disease; diarrheal diseases; respiratory affections."—(Wilcox's *Material Medica*)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†
Alabama*	S. W. Welch, Montgomery	Montgomery..... Jan. 14
Arizona*	A. H. Williams, 219 Goodrich Building, Phoenix	Phoenix..... Jan. 7

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

The Leading Physician of Quebec a Century Ago.—According to Ahern this was J. Mervin Nooth, an Englishman and Fellow of the Royal Society, who arrived in Quebec in 1786 as military physician in Lord Dorchester's command. He had practised in Halifax and New York before the American Revolution. He became general superintendent of all of the hospitals in the Province of Quebec and was appointed to investigate the mysterious "Mal de la Baie" to succeed Bowman after the latter's death in office. His report, which would have been important, has unfortunately been lost. He was also a director of the Quebec Agricultural Society. He died in Bath, England, in 1828.—*Le Bulletin Médical de Quebec.*

CLINICAL FEATURES OF THE RECENT INFLUENZA EPIDEMIC.*

BY CHARLES EDWARD NAMMACK, M.D., LL.D.,

NEW YORK.

MEDICAL DIRECTOR, FOURTH DIVISION, BELLEVUE HOSPITAL; VISITING PHYSICIAN TO ST. VINCENT'S HOSPITAL; SENIOR SURGEON OF POLICE, CITY OF NEW YORK; PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE.

IT is very unfortunate that when the recent pandemic reached New York it was called by a new name. The term "Spanish Influenza" connoted, in the lay mind, a new and mysterious visitation, and the mysterious is always terrifying. When the headlines of the newspapers and the placards in the street cars blazoned forth this new designation, it is small wonder that a large proportion of the people, and these by no means the least intelligent, should become panic-stricken. This panic was assisted by the entirely undeserved criticism leveled at the Health Officer of the Port, and at the City Commissioner of Health, especially by their official predecessors. It was assumed that our Board of Health should have possessed some omnipotent powers by which they could exclude the atmosphere from the lungs and homes of city dwellers. The history of previous pandemics, air-borne over the whole world, was entirely ignored by these believers in the theory of personal contact as the only means of spreading the disease. The history of the present pandemic shows that communities entirely isolated have been reached by the infection. The *New York Times* of the day this is written gives an account of the heavy toll of lives in Seward Peninsula, Alaska, in which 175 out of 250 Eskimos died, and 75 out of 85 soldiers at Fort Davis contracted the disease. Another column of the same paper records the death in Auckland, New Zealand, of a New Yorker from pneumonia following influenza. Its spread on the Atlantic seaboard has been equally extensive, and the City of New York, although sorely tried, has fared better in morbidity and mortality than any other important port. This visitation of 1918 came at a time when all the world was suffering from profound physical, mental, moral, and financial depression. Scarcely a home in New York but has its star in the window, and while we bore our sorrows and deprivations with stout hearts and summoned all our conscious will power to sustain the possibilities of death and disaster, it cannot be denied that subconsciously every American soul was carrying the shadow of anxiety.

*Read before the Society of Alumni of Bellevue Hospital December 4, 1918.

Morbidity.—The morbidity statistics of the Health Department cannot be accepted as accurate, because many overworked physicians entirely neglected to report many of their cases. Those of us who were in general practice during the epidemic of 1889-90 will remember the long hours, the hurried visits, the hasty diagnoses mostly made from the patients' symptoms. But at that time the medical profession was not depleted, and when a colleague fell ill it was usually possible to find another willing to take up his work, and the people generally were able to obtain adequate medical advice and nursing. It is difficult to state at present what percentage of our city population were attacked in this epidemic, and whether it will equal or exceed the 40 per cent. credited to 1889-90. Some idea may be gathered from bodies of men and women whose diseases are made matters of record and whose duties and environment, including exposure to the disease, are similar. My own practice includes the supervision, when sick, of all the members of the city police force residing within a designated territory, to wit: the east side of the city from Twenty-seventh to Seventy-ninth Streets and Fifth Avenue to East River, and the west side of the city from Fifty-ninth to 110th Streets, and from Central Park to the North River. These men are between 21 and 55 years of age, live in tenement and apartment houses of the comfortable class, are well fed, warmly clothed, and have sufficient hours of rest, under a new time schedule which happily had been put into operation just before the epidemic started. My first case reported sick on September 14, my last on November 8, thus showing a duration of the epidemic of eight weeks. My highest sick list during this period was 6 per cent. as against our usual non-effective sick rate of 2.3 per cent. Through the courtesy of Chief Surgeon Patrick J. Murray, I am able to report that the total number of cases among the 11,000 members of the entire uniformed force, in all boroughs, was 1266, or 11½ per cent., of influenza, with a mortality of 0 per cent, and 118 cases of pneumonia, or 1 per cent, with a mortality of 45 per cent. These numbers include all the cases developing between September 14 and November 16, 1918.

The 374 female nurses of Bellevue Hospital developed 149 cases of influenza, of which 13 became complicated with secondary pneumonia, causing 7 deaths. I may be pardoned here for bearing testimony to the unswerving loyalty and tireless devotion shown by the nursing and interne staffs of Bellevue Hospital to their patients. The names of three of our house doctors have been added to the Roll of Honor of those who died in the discharge of duty, duty no less glorious than if encountered on

the field of battle, or with the colors, where many of their former colleagues now are, upholding the traditions of old Bellevue.

Age.—As in previous epidemics, no age can be said to be exempt from the infection. In my private practice, I have had a case at 18 months, and one at 91 years, both recovering, although complicated with bronchopneumonia. The majority of cases, however, have occurred between 15 and 45 years.

Immunity.—It is thought that those who lived through the epidemic of 1889-90 acquired a relative immunity to this attack. My own experience would bear this out.

Etiology.—The overwhelming rush of cases into Bellevue, and the depletion of our nursing and house staffs incident to war, left little time for bacteriological studies. In cases where they were made, many other organisms as well as the Pfeiffer bacillus were found, the most frequent being the *Streptococcus hemolyticus* and the pneumococcus. Inasmuch as invasions by these latter organisms cannot be differentiated clinically from that caused by influenza bacilli, time, which was urgently demanded for the care of patients, could not be spared for laboratory work. Pathologists, male and female, were assigned to ambulance duty, and medical students to ward work.

Pathology.—If we exclude the cases in which pneumonia became a complication, we have no pathological data. In my opinion, uncomplicated influenza does not kill unless injudicious attempts are made to relieve pain by opiate dosing, or to reduce temperature by coal-tar products. I am convinced that every death certificate which gives influenza as a cause of death is a confession of failure to find a complicating bronchopneumonia. In consultation practice I often find it difficult to convince a physician that pneumonia is present because we cannot demonstrate dullness and râles. Yet many persons have died during the present epidemic in whom neither was evident, but instead there existed that acute generalized infectious septicemia which *is* pneumonia, either with or without a localized expression in the lung. In some of the fatal cases, Symmers has found hemorrhagic confluent lobular pneumonia, not detectable during life by ordinary physical signs, and presenting many variations from the ordinary type of septic or croupous pneumonia.

Symptoms.—The incubation period is undoubtedly short, probably 2 or 3 days. Most cases begin suddenly with chilly sensations, fever, headache, general pains, and a feeling of marked prostration, which is strikingly in evidence. Subsequent symptoms depend upon the system of organs involved and the disease resolves itself into various types which may be classified as respiratory, nervous, gastrointestinal, circulatory, genitourinary, and those particularly affecting the eye and ear. A detailed recital of these would severely tax your patience and would be entirely unnecessary to this audience. Of the various complications, bronchopneumonia has stood easily at the head during the recent epidemic as regards both frequency and mortality. The lungs are usually invaded by extension from the bronchi, this invasion beginning about the fourth day. Its diagnosis is often difficult or impossible, as the usual objective signs of pulmonary consolidation may be entirely lacking. On the other hand, signs of consolidation may be evident early and may long outlast the fall in temperature, and give rise to a suspicion of fluid. This should be verified or disproved by early exploratory puncture. Cough and expectoration may also persistently remain for several weeks and arouse a fear of developing tuberculosis. In these cases I have found a tablet of terpin hydrate, creosote, and strychnine most useful.

In the domain of the nervous system there is scarcely a symptom or clinical entity which has not been assigned to a preceding influenza. Some cases, especially those in children, begin with marked gastrointestinal symptoms, but these probably result from the toxemia rather than from any specific action of the invading organisms upon the digestive apparatus. The effect of the influenzal poison on the circulatory organs is usually one of inhibition, and a proportionately low pulse rate has been a marked incident of my cases. Therefore I do not add to this depression by administering an inhibitory drug like digitalis. The leucocyte count in uncomplicated cases is low, this leucopenia being a valuable differential point in diagnosis. The genitourinary symptoms are not marked except in the rapidly fatal fulminating cases of pneumonic septicemia which at autopsy will show hyperemia and acute parenchymatous kidney degeneration. As compared with the epidemic of 1889-90, there have been comparatively few ear complications. I have seen in private practice but one case of double otitis media—the 14 year old son of a physician—and no case of mastoiditis. Invasion of the accessory sinuses has also been far less frequent than in previous epidemics.

Diagnosis.—During the prevalence of epidemic influenza, we are apt to classify hastily all cases of catarrhal respiratory inflammation under that heading. But the suddenness of onset, the severe general pains, the very marked feeling of prostration and weakness, especially in robust individuals, and the number of persons affected often in the same household, furnish sufficiently distinctive points. When pneumonia develops, the picture changes and may require careful study for its recognition. Typhoid fever and acute miliary tuberculosis will give most trouble in differentiation at the outset, but will soon become plain by the development of their characteristic features.

Prognosis.—Uncomplicated influenza has almost no mortality. Of 55,623 cases in the Prussian Army during the pandemic of 1889-90, only 59 died from influenza, and of these 42 had pulmonary symptoms. In Munich death was ascribed to influenza in 133 cases out of 22,972, and 69 of the 133 had pulmonary disturbance, and 88 of them were between 51 and 90 years of age. Every complication that may develop brings with it its own dangers, and the pneumonia that has accompanied or followed the present influenza cases has seemed to be particularly virulent. Autopsy protocols will show how futile have been our attempts to conquer disease of this type.

Mortality.—The Health Department figures, as quoted in the *New York Times* of November 17, 1918, give a total of reported cases of "Spanish in-

fluenza" of 127,999 and of reported deaths of 10,428. I believe that 128,000 cases does not truthfully represent the percentage of our 5,000,000 inhibitants that were affected. A 2½ per cent. ratio would not explain the widespread sickness and suffering. Neither do I believe that the present epidemic carried a death rate of 8 per cent. of cases of uncomplicated influenza. That is contrary to our experience in all the hospitals. The same figures give 18,932 reported cases of pneumonia with 9,450 deaths, a mortality of 50 per cent. This agrees with our hospital records. The Fourth Division of Bellevue Hospital treated 338 cases of influenza with no deaths, and 312 cases of pneumonia with 195 deaths, or 62½ per cent. Bellevue patients are made up of the poorest classes of the city, comprising the underfed, scantily clothed, overworked, and, I regret to say, in many cases, the rum-soaked and syphilis-ridden members of the community. The statistical record of the entire hospital shows 1,993 cases of influenza with 428 deaths, or 21½ per cent.; 693 cases of pneumonia with 482 deaths, or 72 3/7 per cent. A great many of the Bellevue cases are admitted in a moribund condition. The statistics just issued by the Government Bureau of the Census group the deaths from influenza and pneumonia together, and show 82,306 fatalities in 46 cities having a combined population of 23,000,000. In St. Vincent's Hospital the number of cases treated in the medical services from September 16 to November 16, 1918, was as follows: Influenza, 199 cases; 0 deaths, mortality 0 per cent.; pneumonia, 151 cases, 58 deaths, mortality 38 per cent.

Prophylaxis.—I have administered the preventive vaccine furnished by the Board of Health to many of my patients and it has given them great mental comfort like that blessed word Mesopotamia in the Highland lady's system of theology. One mother and her son developed the disease two days after the first injection, but in a much milder form than the cases already existing in that household. All my other injected patients escaped the infection. The general measures of prophylaxis are those we would adopt in the case of any infectious disease and need not be gone over here.

Treatment.—As there is no specific for influenza, treatment could be dismissed in a few words were it not for the fact that many cases are grossly maltreated; generally by the patients themselves, or by obliging drug clerks, in following the alluring promises of the various sure cures and preventives so widely advertised. I am confident that a much lauded German coal-tar product has been responsible for more deaths than has so-called Spanish influenza. I regret that some of our own profession advocate its use, in doses up to 60 grains a day. Why any one should want to add to the poison of a disease so depressing as that of influenza, a poisonous depressing drug, passes my comprehension. Influenza demands isolation, ventilation, elimination, and sustentation. Only these, and nothing more. But we are expected by the patient and his family to order some prescription for his pain and for his fever. Pain is "the prayer of the nerves for healthy blood," and the four measures I have mentioned will soon free the blood from the toxin which is poisoning it. Fever is "a specific reaction against injurious materials which affect the tissues and is, in its essentials, a protective reaction." Will the patient accept these definitions instead of physic? He will not. Therefore, if I must get the collaboration of the druggist in the management of the case, I order a combination of ammonium carbonate, grs. 5, to facilitate expectoration, ammonium salicylate, grs. 5, to mitigate pain with the least depressing effect, and aromatic wine of erythroxylon coca (National Formulary) one-half ounce as a nerve stimulant and muscle invigorator. This wine is one introduced by the American Pharmaceutical Association many years ago to take the place of a proprietary wine advertised to be in use by most of the crowned heads of Europe. Plain port wine is probably equally effective and more generally used at the present time, the example of crowned heads not now being so eagerly followed. The formula itself is very popular with the patients in Bellevue, where it is known as the Anti-Grippe Mixture.

379 Park Avenue.

THE ARSENICAL TREATMENT OF SYPHILIS.

By B. SHERWOOD DUNN, M.D.,

PARIS, FRANCE.

OFFICIER D'ACADÉMIE; MEMBRE CORRESPONDENT SOCIÉTÉ OBSTETRIQUE ET GYNÉCOLOGIQUE DE PARIS; SURGEON TO THE SERVICE DE SANTÉ MILITAIRE DE PARIS; PHYSICIAN TO COCHIN HOSPITAL

In a paper recently published in this journal I described the diverse forms under which mercury has and is being used as a curative agent in syphilis, giving a history of the development of treatment by this agent and coming to the period of the discovery and introduction into our therapeutics of arsenic as the paramount remedy with which to combat this dire disease. In this paper I purpose giving a careful review of the various arsenical preparations that have survived the test of experiment and have taken place among the accredited remedies of real merit.

Since the advent of "606" active research has not ceased in the realm of chemiotherapy, seeking to discover a more certainly destructive agent for the spirill of syphilis. In the experimental work upon metals as bactericidal agents the names of Armand Gautier, Laverin, Thomas, Kopke, Louis Martin, R. Kock, Salmon, Mesnil, Danysz, Nicolle, and Morgenroth, and prominently that of Ehrlich and his collaborators and students Karren, Vanden Branden, and Mlle. Leupold have been more or less constantly before the profession.

In 1913, Mouneyrat published an important work upon arsenotherapy and his discovery of galyl, or tetraoxydiphosphotetraaminodiarsenobenzol, which added to the phosphate of arsenobenzol possesses a concentration of arsenic greater than is found in neosalvarsan and marks, an important advance in the treatment of syphilis.[1]

About the same period the new remedy discovered by Danysz began to be experimented with in the clinic of Cochin Hospital—but we will consider the well known arsenical preparations in the order of their appearance.

Salvarsan or 606 (of Ehrlich and Bertheim: experimented with upon rabbits by Hata). This remedy was first used upon the human subject in

France in September, 1910. It is a yellow powder, containing 34 per cent. of arsenic; soluble in water in a clear yellow liquid with hydrochloric acid. In the presence of soda the chlorhydrate decomposes, forming Na C of an insoluble base; if an excess of Na O is added the base is redissolved, the two oxhydrils OH are replaced by Na O and form a soda base.

At first Ehrlich practised a single intramuscular injection, expecting it to cure syphilis by one powerful stroke (therapia sterilisans magna). Employing a dose of 0.30 to 0.60 gm. and even going as high as 1 to 1.20 gm. In following this practice some made use of an alkaline solution (Ehrlich, Herxheimer), some a neutral emulsion (Wechselmann, Blaschko), and some an acid solution (Duhot). Dorsal injections which gave rise to numerous accidents soon gave place to deep gluteal intramuscular injections. At the end of two months of experimentation of the single injection it was abandoned, the initiative being taken by Ehrlich himself, who recognized that a single dose even in amount that passed the limits of safety did not suffice to destroy the spirochetes. Hudelo treated 24 patients by the single gluteal injection,[2] and in less than six weeks 6 returned with full secondary symptoms. The single injection also gave rise to much inflammation and in some cases deep seated gangrene of a grave character.

Balzar has remained faithful to the intramuscular injection of salvarsan, as have also Kromayer, Levy-Bing, Lafay, and Queyrat using an oil emulsion. Balzar injects 20 gm. suspended in one cubic centimeter divided into two doses, injecting one-half into the mass of sacrolumbar muscles on each side. These injections give rise to pain that endures for a few hours; the reaction is not severe and is well supported. The injections are renewed weekly in series of 5 or 6, as with gray oil, and these series are repeated after intervals of repose of one and two months. Balzar has pronounced himself well satisfied with the results he has obtained, both clinical and serological. The administration of this remedy by the buccal and rectal routes has been largely abandoned.

To-day 606 is chiefly employed in intravenous injection, using a soda base, by dissolving the dose of 606 in 30 to 40 c.c. of a 15 per cent. solution of chloride of sodium for 10 gm. of the salt, adding 2 drops of HCl to precipitate the base (mayonnaise emulsion), then 2 drops more to redissolve the base (yellow Chartreuse liquor), and one drop supplementary to assure a perfect alkalinnation. The *crises nitritoides* and the congestive accidents (menigocerebral) have been attributed to an insufficient alkalinization which has not saturated the 2OH. Finally, distilled or sterilized water is added at the time of using in the ratio of 50 grammes for 10, 100 for 0.20, 250 for 0.50 gm. of the salt.

In November, 1910, Ehrlich advised increasing the injections from one to three, employing 0.30 to 0.60 gm. with a period of five to six days intervening. Milian advised four injections over a period of nineteen days, employing a total of 1.70 to 2.10 gm. Leredde advised that following the third injection the dose be determined in the ratio of 0.01 to the kilogramme of the patient. Little by little the number of injections has been increased. Ravaut gives from 6 to 10 for each cure, but in feeble doses.

Under all of these methods the results obtained were remarkable. If the subject was put under treatment during the primary period, in a few days the chancre became cicatrized and the disease seemed to be aborted. No secondary accidents appeared of either roseola or mucous plaques. If the chancre was less than twenty days old and the Wassermann test was negative before the treatment it remained negative after the treatment. If the chancre was more than twenty days old and the Wassermann had had time to become positive it became negative at the end of the cure. Certain authorities believe that when these conditions exist after the administration of 2.20 (Querat) complete sterilization exists, as shown by a persistent negative Wassermann, and absolute integrity of the cerebrospinal fluid over a period of years. Yet as a safe precaution they counsel the giving, from time to time, of 0.30 gm. of 606, called the "reactivation,"[3] thanks to which if the patient has not been sterilized, his Wassermann again becomes positive and he is again subjected to a cure of from thirteen days (Milian) to as much as thirty days (Leredde).

One formal proof of radical cure cited by Milian is the observation of a patient who, cured of his chancre by 606, returned three months later with a fresh primary chancre resulting from intercourse with his wife, who was found in a virulent condition of the disease, having submitted to no treatment.

We will later consider what deduction may be made from this reinfection and its significance.

When the patient is brought under treatment by 606 at the beginning of the secondary period, or later, when the roseola is in full bloom accompanied by cutaneous eruption and mucous plaques, 606 will in a few days cicatrize the mucous patches and cause the disappearance of the cutaneous symptoms. Also, but upon condition that the cure has been fully extended (Leredde estimates this at a minimum of nine injections), the Wasserman which was formally positive, slowly returns toward the negative and the cure should be continued until this complete result is secured. But is this result sufficient? It is an important point to observe that at this stage of the disease, the cerebrospinal fluid is always affected by the treponeme and it is exceptional to find it returned to its primary integrity after a single course of treatment by 606; as a rule it still exhibits a certain degree of alteration (hypertension, albuminosis, lymphocytosis). It is necessary after a period of repose, which, according to Leredde, ought not to surpass three weeks or, according to Jeanselme, not more than two months, to undertake a second course?

In our opinion, if after the close of the first treatment the blood analysis and lumbar puncture give negative results, we should discontinue all treatment but control the conditions by repeated examinations of the patient and by the "reactivation" test, at first every month, then every two months, then every six months, and then from year to year for at least five years. If on the contrary, the tests at the close of the first treatment, do not afford full satisfaction we should subject the

patient to a second course at the end of four to six weeks.

Hudelo reports[4] that from 1910 to 1914 he used the 606 treatment upon several thousand cases. At the outset he employed a series of three intravenous injections (1.55 gm.), increasing as he advanced in experience with the remedy to four and six (2.85 to 3.10). Although in all his primary cases he secured favorable clinical and serological results (absence of roseola and mucous plaques or other secondary accidents, with negative Wassermann), he found the majority were not cured; many returned at the end of a few weeks or months either with a positive Wassermann or with secondary reaction, cutaneous or mucous, the secondary period having simply been retarded. With those patients who came in the secondary period and whom he submitted to successive treatments with periods of repose of two months intervening, he arrived at a result of complete sterilization, both clinical and serological, which with some of them had continued from 1911 to the date of his communication.

Jeanselme[5] treated 14 pregnant women with 606 at different periods of gestation, who as a result were all delivered of children who were still living at the end of eight days when they left the obstetrical wards. The treatment by mercury or by iodine and mercury does not give like results.

With the advent of the neosalvarsan, a modification of 606, the number of practitioners who have remained faithful to the latter is limited, and they remain so because of what they term its *"mordant"* (destructive) qualities and the durable results it furnishes.

Neosalvarsan, or 914 of Erlich, first appeared in 1911. Its preparation for use is free from complicated manipulation. It is a powder of yellow saffron color, soluble in water. The solution is rapidly altered by exposure to the air, taking on a cherry red color and becomes toxic. It contains 21 per cent. of arsenic and corresponds to two-thirds of its weight of salvarsan.

Gaston experimented with intramuscular injections of this remedy, which were found to be too painful for endurance and they were abandoned. Wechselmann employed concentrated subcutaneous injections of 50 per cent.

Balzer adopted the same method as with 606, injecting every seven days 0.30 gm. in two injections of 0.5 c.c. each, first in the lumbar and then in the gluteal region at the point of Schindler. The pain lasted only a few hours, and was supportable. His series of injections comprised four to five renewed the same as for gray oil or calomel.

Intravenous injections, universally employed today, are made with the salt dissolved in distilled or sterilized water: at first one centigramme of 914 was dissolved in 1.5 c.c. of water or 45 c.c. of water to 0.30 gm. of the salt. Revaut[7] proved the safety and advantage of a solution much more concentrated (10 to 17 c.c. of water to 0.45 to 0.90 gm.)—to-day this has been reduced to 4 and 5 c.c. and even to one.

The dose employed per injection is from 0.30 to 0.75 gm. In women the dose has been from 0.30 to 0.90. Leredde has used upon certain occasions from 1 to 1.5 gm.

The interval between two injections was at first fixed by Schreiber at two days. To-day it is put at from five to seven. As with 606 each cure is made by progressive doses, commencing with the minimum and increasing with each dose for five to ten doses, giving a total of from 3.30 to 6 and 7 grammes.

The general direction of treatment by 914 is the same as with 606; the clinical and serological results are identical; the after care is the same and by the same procedure (examination of the blood and lumbar puncture).

Hudelo in his use of this remedy has had the same experience as with 606. Since May, 1912, he has tried it in his Clinic upon a great number, and even in those who have been subjected to an extended medication comprising 6 to 7 grammes the cure has proved only apparent. Numbers have returned after a cessation of a few weeks or months with secondary symptoms (roseola and mucous patches) with an increasing Wassermann.

In the case of those who were negligent and irregular in treatment (and the number is great in every clinic) he was struck by the oftentimes intense symptoms of relapse (cutaneous, mucous, hepatic, nervous), always accompanied by an increasing Wassermann. In his opinion the recurrence of symptoms following treatment is more frequent with 914 than with 606.

Galyl or 1156.—Numerous autopsies have shown that where 606 and 914 were the cause of death there existed in every case hemorrhagic centers showing the toxic qualities of these salts. Moreover there are countless cases of serious nervous symptoms when the resisting power has been passed by the size of the dose, according to the idiosyncrasy of the individual.

With a desire to overcome these disadvantages, Mouneyrat in 1913 sought to find an arsenical remedy analogous to these which should not have a vasodilator or a neurotropic action, and brought out two preparations, galyl or 1156 and lutyl or 1151. These products were experimented with by de Beurmann and Tanon.[8] The first only has remained in use—it is a tetraoxy-diphospho-aminodiarsenobenzine, representing 35.3 per cent. of arsenic and 7.2 per cent. of phosphorus. It is an inodorous yellow powder, which dissolves in a saturated solution of bicarbonate of sodium; thus dissolved it can be put in closed tubes and kept indefinitely. It is administered in a series of uniform dosage, not in progressively increased dose as with the other remedies. At first the cone comprised 1.50 gm. of the salt administered in three doses by intravenous injection, with eight days interval between each; at present a total of 2 grammes is given but in doses not surpassing 0.25 with the same intervals. It is also administered by intramuscular gluteal injection in an oil monstrum.

Galyl has proved its right to a place among the arsenical preparations, but in my opinion possesses no advantage over others and demands the same degree of caution in its employment, and it cannot be said to have accomplished the prime object of its author, viz., the elimination of the toxic qualities possessed by its predecessors.

We now come to a consideration of the last and in some respects the most important of arsenical

products that has appeared in the search after an agent that will completely destroy the disease germ and yet do no harm to the patient.

Luargol or 102 of Danysz.—As early as 1913 Fournier (Louis) of Cochin Hospital commenced the use of the remedy and when I joined his service in June, 1916, they already had recorded more than 4,000 cases treated and in some instances with remarkable results.

Dr. M. Danysz of the Pasteur Institute has studied the therapeutics of syphilis for many years, and after a long line of experimentation, added a new element to a combination which from the evidence already accumulated would appear to be the most important and effective of the remedial agents, so far discovered. He first combined silver with losine and obtained a precipitate which was dissolved by the addition of chloride of sodium. This product showed a marked antisyphilitic action, but its deleterious effect upon the injected veins of rabbits precluded its clinical employment. After progressive experiments M. Danysz[9] mixed a solution of nitrate of silver with an aqueous solution of the chlorhydrate of dioxydiaminoarsenobenzol, and obtained a limpid liquor more or less dark in color, following the amount of silver employed.

In treating this liquid with chloride of sodium or any other electrolyte, there was produced a floculent precipitate and testing the acidity of the superimposed liquid, the reaction showed no appreciable change. Treated with sulphuric acid, there was precipitated from the composition an abundant clear yellow sediment and the superimposed liquid showed only traces of silver and arsenic, proving that these elements were fixed by the dioxydiaminoarsenobenzol.

M. Danysz then had the idea to replace the chloride, the therapeutic action of which was contraindicated, by the bromide or iodide of silver, which in themselves possess microbicide qualities. He mixed solutions of these two salts with cyanide of potassium in a solution of dioxydiaminoarsenobenzol. The dry product gave the following:

Bromide mixture: Ag. 10.06; Br. 8.14; As. 26.99; SO_4H_2 15.97.

Iodide mixture: Ag. 10.50; 1.11.47; As. 26.80; SO_4H_2 15.97.

In an earlier paper upon this subject[10] I cited the fact that Ehrlich had made a series of studies analogous to those of Danysz, of which fact the latter was ignorant, and that he arrived at the formation of his combination before he became aware of the work done by the former.

Ehrlich named his composition K3. Dr. Milian states that Ehrlich personally confided to him a certain number of ampouls to study its action in syphilis, and the result of his observations was that it tended to produce attacks of apoplexy, similar to that of salvarsan and was often followed by "*crises nitritoides*," and was a dangerous remedy. Fortunately, so far none of these evil results have folowed the administration of the "102" of Danysz.

The "102" is a composition of bromo-argentic-antimony of arsenobenzol. In hope to augment the specific action of the arsenobenzol bromo-argentic (product 88[3]) Danysz introduced a certain quantity of antimony in the form of the trichloride ($SbCl_3$); he thereby obtained the sulphate of dioxydiaminoarsenobenzolate of the bromide of silver and antimony (product "102" $C_{12}H_{11}O_2N_2AS_2$) 2Ag. Br. SbO. $H_2SO_4)_2$ as near as can be determined, for the molecular formation is so intimate it is difficult of exact determination.

The following table shows the comparisons:

	Theory per 100.	Analysis.		Average.
		One.	Two.	
C	19.88	19.87	19.82	19.84
AG	7.45	7.39	7.41	7.42
Br	5.52	5.50	5.56	5.53
As	20.70	20.68	20.52	20.60
Sb	8.29	8.18	8.20	8.19
S	8.86	8.89	8.85	8.87

Toxicity. The dioxydiaminoarsenobenzol bromo-argentic or "88[3]" is toxic in the dose of 10 centigrams per kilogram to rabbit, guinea pig, and mouse. The same product with antimony added or "102" is toxic in the dose of 25 centigrams to the kilogram of the mouse. The accumulating evidence goes to show, that "102" has greater and more beneficial action than any other of the arsenical remedies in trypanosomiasis.

In rabbits infected with surra, the malady develops in about the same manner as in the large mammals and in man. Following a period of four or five days of incubation, the subject has a rise of temperature of 1° to 1.5° C. and commences to lose flesh. Thirty or forty days after the invasion, lesions appear upon the skin and mucous membranes, followed by nervous manifestations".

In treating animals during the different periods of this disease by the arsenical preparations (atoxyl, arsenophenylglycine, arsenobenzol, "88[3]," "102") in doses of one centigram per kilogram of weight, all were cured by any of these products during the period of incubation.

During the second period, only a certain proportion were cured by atoxyl, arsenophenylglycine, and arsenobenzol, whereas "88[3]," and "102" cured at this stage all the rabbits treated.

During the third stage of the disease "102" cured 5 out of 6 treated with the dose of one centigram to the kilogram. It required double this dose of "88[3]," to obtain the same result and with the three other products mentioned no appreciable benefit resulted.

M. Danysz discovered in his experiments another important and valuable element, viz., That with "102," as well as "606" a better and more certain result is secured by a small dose frequently repeated rather than massive doses, at no matter what periods between; his conclusions have been verified in the treatment of syphilis by Professor Fournier with "102" in Cochin Hospital, where commencing with a small dose it is gradually increased to a given limit at the close of the treatment.

I think a clearer conception of the principles underlying the experimental investigation of this subject can be given the reader by quoting in its entirety a recent communication received from M. Danysz which he furnished at my request.

"The therapeutic value of the arsenical compounds have been known a long time and since the investigations made by Armand Gautier, have been

given greater prominence than other of the mineral compounds. The good effects of the cacodylate and methylarsinate of soda as well as atoxyl and hectine of arsenobenzol in malarial fever, trypanosomiasis, syphilis, and other parasitical diseases have long been known, and an interesting fact to note for future research, is that it is not so much the quantity of arsenic as the structure of the molecule of which it forms a part that determines its beneficial effect.

"For instance; the cacodylate which contains 48 per cent. of arsenic, has no streilizing action upon the trypanosomes or treponema, while the dioxydiaminoarsenobenzol which contains only 40 per cent. has a powerful action upon these parasites: *but all of the mineral or organic arsenical compounds seem to have a common defect; the organism and parasites soon become accustomed to their presence so that the sterilization of the organism becomes difficult and sometimes impossible and the apparent cure is sooner or later followed by a new outbreak.*

"To overcome this difficulty the idea occurred to me to combine the arsenical compounds with elements known to possess powerful action upon parasites, to which the system does not show a tendency to become accustomed, notably the metallic salts.

"I realized the first practical result in the combination of dioxydiaminoarsenobenzol with the silver salts[2] and following this with the copper salts[3] and experiments upon animals have shown these compounds to be considerably more active upon trypanosomes and treponemes than that of arsenobenzol alone.

"We have known some time that arsenobenzol could be combined with quicksilver, gold, platinum, and almost all the metals and from a chemical point of view, these compositions possess great interest.

"The dioxydiaminoarsenobenzol is an irritant product for the reason that its chemical components are not in affinity, but by the addition of two molecules of some other substance the composition is brought into a condition of greater stability and harmony. However, from a therapeutic point of view, it is not desirable to add to one molecule of arsenobenzol two of a silver salt or of quicksilver per thousand, for then the dose of these toxic metals would be too strong to produce a curative effect.

"As the quantity of arsenic could not be safely augmented, in searching for a substitute I finally added one molecule of antimony which by its chemical and therapeutic properties, resembles arsenic very much.

"*En résumé*, the arsenostibio argentic compound, which is designated luargol or "102," contains a a little more of arsenic and antimony together than arsenobenzol contains of arsenic, and besides, contains about 13 per cent. of the bromide of silver."

Experiments upon animals have fully confirmed the theories regarding this product and have shown that luargol is more stable, more active, and relatively less toxic than arsenobenzol[4].

For certain trypanosomiases and in particular for surra the relation between the dose tolerated and the curative dose is 80 to 1: for the trypanosoma Gambieuse 100 to 1; whereas for these same trypanosomiases, for atoxyl is 4 to 3, for arsenophenylglycine is 3 to 1, and for arsenobenzol is 10 to 1.

For sleeping sickness luargol is thus shown to be 75 times more active than atoxyl, 30 times more active than arsenophenylglycine, and 10 times more active than arsenobenzol. In addition to this it has been proved that luargol will cure mice infected with trypanosomiases dimorphon, where they are absolutely resistant to the action of the three other products mentioned.

In experiments made upon rabbits with syphilis, luargol caused the treponemes of the chancre to disappear in 24 hours in doses of 2 to 3 milligrams to the kilogram of the animal.

The same results are obtained in the treatment of men, viz., disappearance of the treponemes of the chancre and of mucous patches in 24 hours after a single injection of 0.10 to 0.15 centigrams, which result is obtained with arsenobenzol only by the employment of a dose two to three times this strength; and it has been found possible to employ luargol or "102" where other organic compositions of arsenic are not tolerated because of the much stronger dose required.

The chief advantage possessed by "102" over the previous arsenical preparations is its benign action in the presence of grave lesions of the central nervous or circulatory system. We have records of many fatal accidents following the administration of "606" and "914" in the presence of these lesions; whereas it has been shown in the treatment of many thousands of cases in Cochin Hospital, that "102" can safely be injected at any and all stages of the disease even in tabes with commencing ataxia, without eveil results; the prompt action of the remedy in arresting the progress of the disease is invariably the same, and so far no fatal accident has followed our employment of this remedy in more than 6000 cases in the most advanced stages and worst phases of the disease.

The limits of this paper will permit of the record of only a few of the worst cases treated.

The first reports of results upon the human subject with "102" were presented before the Paris Academy of Science by Professor Laveran[5] being a résumé of the experience of Drs. Fournier, Renault, and Guénot.

One of the early cases showed the improvement following five injections of salvarsan 0.50 each and proceeded to a complete cure under luargol commencing from the first injection. Drs. Dalimier and Levy-Frankel, army surgeons reported to the military authorities upon 22 cases treated with luargol. Three phagadenic chancres, one of the size of the palm of the hand, cicatrized in 15 days; dose for each 1 gram. One gangrenous chancre with edema of the penis; cicatrization in one week after 0.60 grams of luargol.

Secondary period, ulcerous syphilides, uninfluenced by gray oil, cured in 12 days after 0.40 gram. of luargol.

Tertiary period, two malignant cases. One ulcerated gumma of sternomastoid, size of an orange, cured in 11 days after 0.90. One, a hardened testicle softened in ten days and complete cure after two months.

Syphilitic myelitis. Brown-Séquard syndrome, incomplete on right side, which side is paralyzed.

Exaggerated reflexes with epileptoid tremors; positive Babinski sign both sides, abdominal reflexes abolished; defensive reflexes exaggerated to second dorsal vertebra; purulent cystitis, retention of urine, fecal incontinence. First injection of luargol

Fig. 1.—Before treatment.

Jan. 28. On Feb. 9, after four injections, patient can stand alone. Feb. 14, can walk.

Syphilitic aneurysm of aorta; history of chancre twenty-five years back. Examination showed marked depression in recumbent position: thoracic pains, insomnia; double murmur at aortic orifice pulsation in the substernal space.; double heart beat of Stokes pronounced; left pulse more feeble than right. First dose of luargol Jan. 19. Treatment continued every third day to Feb. 25 with total administered of 1.20 gram. Oppression and insomnia gone, rough murmurs now soft, pulse equal, pulsation of aorta now barely perceptible. Patient so much improved he left the service promising to return but has not since been seen.

The patient whose photograph is shown in Fig. 1 entered Cochin Hospital, May 5, 1916. His chancre appeared Jan. 18, 1916, Feb. 3 Wassermann test positive. A local doctor gave him 49 injections of hectine, one every day, the last 9 being of 0.2 gm. each. During this period he also took 30 pills of protoiodide of mercury and 250 grams of Guilbert's syrup (a mixture of mercury and potassium iodide). Treatment continued from Feb. 10 to May 2. Chancre disappeared March 20.

Patient had the rupial syphilides as shown upon entrance. He was given injections of luargol, Mondays and Thursdays beginning with 10 c.c. and increased to 30 c.c. at the fifth injection, when photograph Fig. 2 was taken. Amelioration was apparent after the first injection: crust dried and fell off following the second injection. He was discharged cured at the end of 21 days.

We usually commence with an initial dose of 5 to 10 c.c and increase to maximum of 35 c.c, but usually to not more than 25 c.c., 1 c.c. representing 1 centigram of the salt.

Our experience with "102" confirms our opinion of its excellence in the treatment of syphilis, but particularly in the tertiary and grave forms of the disease. Containing the smallest proportion of arsenic of any of the arsenical preparations, it can with safety be administered at any stage of the disease, although none of the arsenical products should be given in the presence of albuminuria or diabetes.

Of late we have followed the treatment by luargol of the tertiary cases, by "606," feeling that the more powerful remedy better insures the future of the patient.

What can we conclude from our study of the arsenobenzines? Can we with safety discard the use of mercury, brought to a degree of perfection after fifty years of experimentation, and replace it entirely with the newer remedy, as is advised by many recognized authorities of the present day?

It is an incontestable fact that the introduction of arsenic into the treatment of syphilis has arrested the attention of the entire profession by the marvellous rapidity with which, in the great majority of cases, it cicatrizes the chancre, the erosive or ulcerous accidents, the mucous patch, extensive syphilides; causing the disappearance of the treponeme after the first does; the contagiousness of the disease is thus caused to disappear in a few days. This alone forms a gain of social importance of the very first order, and if it presented no other advantage this would suffice to give it a leading place in the present day treatment. As a second advantage of prime importance, is the fact that the ability of arsenic to render the patient sterile and non-dangerous in a few days permits of his being hospitalized for a few days only in place of weeks, as in the case of a course with mercury; a patient is much more amenable to hospital sequestration for eight or ten days than for that many weeks. Rendered non-contagious, the patient can return to his usual occupation on condition that he returns to the clinic over a given period of time at regularly fixed dates to complete the cure.

The marked success of arsenic in pregnant women is noticeably superior to mercury and forms

Fig. 2.—After treatment.

a precious agent to combat the infantile mortality of syphilis which is at the actual moment more menacing than at any previous period.

It is claimed that the subjects treated at the commencement of the primary period, before the ap-

pearance of the roseola have the greatest chance of being cured after 2 to 3 grams of arsenobenzol or 5 to 7 grams of noversenobenzol; not only are they free from any further clinical evidence of the disease but their Wassermann and cerebrospinal fluid give completely negative results. As an additional and indubitable proof of complete cure, are cited the cases of reinfection, which are as frequent to-day as they were rare under the former mercurial treatment, and many of these reinfected cases are in those who were apparently cured with only 3 or 4 injections.

Careful observation of these cases does not permit me to coincide with these claims for I have come to the conclusion that, far from being cured, these are cases showing marked affinity to the remedial agent; the disease has been arrested with the first injection, and after the few injections reported, all tests being negative and the patient apparently completely relieved is discharged cured, but he was not cured; the disease was simply "put to sleep," retarded in its progress; a certain nidus of infection, dormant in the system, came to life and the reinfection was simply the external evidence of a fresh outbreak. It must be noted that the reinfection appears only in those treated in the primary periods, there is a notable absence of cases of reinfection among those treated in the secondary period and later[16]. Certainly it ought to be as often observed in those "cured" in the second as in the first stage.

A very important fact bearing upon this question of reinfection is that most of the reinfected cases come back two to four months after they were pronounced cured and this coincides with the delay ordinarily observed in patients who rendered noncontagious and permitted to leave the service upon the promise to return regularly, have been negligent and irregular, who break out with the various mucous and cutaneous accidents, icterus, and various incipient forms of paralysis.

Boyet, Deneux, Desjardins, Gaucher, Fribus, Diday, and Hudelo, have commented upon similar cases that have come under their observation, where there had been no possibility of reinfection, showing the fresh chancre to be simply a relapse. Taking all the evidence into consideration the cases of reinfection resemble very greatly a relapse of the primary condition.

When the treatment by arsenic has caused the disappearance of all cutaneous and mucous signs; has progressively caused the Wassermann to change from H° to H⁵ are we warranted in believing our patient cured, even repeating the test every month, then every two, then every six, and from time to time giving a reactive test injection of 0.30 of arsenobenzol making a serum re-examination at the end of 10, 15, or even 30 days (Leredde)? I am only one among many who do not believe we can assure a patient that he is cured. With the extended history, accumulated over long years of careful notation of the evolution of syphilis, I doubt if at any time, under any condition, we can be certain that a cure has been effected.

Going further, in cases where the patient has presented nervous accidents and upon examination we have found the cerebrospinal fluid affected, can we, after all visual evidence has disappeared, the serologic test become negative, the cerebrospinal fluid become normal, assure the patient indemnity from any further danger attached to the meningocerebral or meningomedullary system? I should not want to commit myself to that assurance; and, even if we felt certain on this point, what is to be said about the future indemnity of the spleen, the liver, the kidneys, the heart, the arteries, or the medullary substance of the bones? The history of long years of accumulated experience of the great teachers past and present has shown the possibility of a point of latent infection resting quiet in any one of these systems, coming to life and virulent manifestation after five, ten, or twenty years, stupefying the patient, who had been assured that he was cured. It is necessary to recoguize that we have to-day no sure and certain means of knowing for a fact that syphilis is cured. Once a patient leaves our care "cured" apparently, our prognosis of his future can be based only upon presumption. Eternal vigilance is the price of safety and in nothing is that truer than in the treatment and care of a syphilitic; we can repose confidence *only* in a chronic examination and treatment as opposed to the most chronic of all known diseases.[17]

It is too soon to predict how large a place is to be filled by the arsenical products in the treatment of syphilis. When we consider that the total of our statistical knowledge of the efficacy of the arsenical treatment extends only over a period of seven years we cannot yet know how many of our "cured" will return sooner or later with renewed manifestations of the disease.

Our experience in Cochin Hospital with the latest of these remedies, luargol or 102, persuades us of one superior advantage it possesses over those that have gone before, viz., there are no contraindications to its use. We know there exist many in the case of 606 and 914 and that they have been the cause of many fatalities, especially when the disease has attacked the central nervous or central circulatory system. We have experienced some remarkably good results in tabes, general paralysis, leucoplakia, lesions of the aorta, and affections of the cranial nerves, in all of which 606 and 914 are contraindicated and dangerous.

We know the immediate good results of arsenic, and perhaps with a more complete knowledge we may find the way to use it to insure the permanency of these good results, but at the moment a great number of syphilographers complain of the numerous cases of relapse after the primary treatment by this agent. We can ask if the administration by intravenous injection, the rapid distribution through the circulation and its equally rapid elimination, permits the medication, mercury as well as arsenic, to destroy completely and effectually the disease germ; the same question arises regarding the intravenous treatment of malaria by quinine.

If arsenic alone cannot effect the complete sterilization of the system, why should we not call mercury to our aid, the efficacy of which has been proved by decades of practice. This is a question that is being asked by leaders forming a new coterie uniting the partisans of mercury with those of arsenic; using arsenic for the arrest of the disease, the rapid cicatrization of the contagious accidents, then after some weeks of repose commenc-

ing the classic cure by mercury. Brocq and Weisser advocate this procedure, and, judging by the statistics recently published[18] of this treatment in the armies, takes the place of honor. It is always possible and permissible to make a new cure by arsenic, in the presence of a return of cutaneous or mucous accidents, or where the system rebels against the mercury or where a rapid and intensive action is called for.

Danysz says of the preparations of arsenic: "The organism and parasites soon become accustomed to their presence, so that the sterilization of the organism becomes difficult and sometimes impossible," and, in my opinion, herein lies the present failure of arsenic alone to procure the permanent results we so earnestly seek; there is therefore well-founded reason for the return of many to the old faith in mercury to realize the permanency of result wherein at present arsenic seems to fail. Among those who have made favorable reports upon this combined treatment are de Lapersonne (ocular lesions), Vaquex (heart and aorta), P. Marie (nervous system). Alternate cures of arsenic and mercury have been tested favorably by Favre and Longin.

In the effort to simplify this combined treatment several combination remedies have been introduced. Enesol (Salicylarsinate of mercury) is injected intramuscularly or intravenously 0.03 gm. per cubic centimeter and 2 c.c. are injected every day or every other day: this remedy has been employed as high as 4 to 5 c.c. per day two to three times per week until ten to twelve injections are made, then one month of repose and repeat.

Hectargyre is a combination of hectine and mercury. Hectargyre A is composed of 0.10 hectine and 0.005 mercury; hectargyre B is composed of 0.20 of hectine and 0.01 mercury per cubic centimeter. It is also made in solution to be administered by the month; 20 drops correspond to 0.05 hectine, 0.005 Hg.

Enesol and hectargyre are well tolerated, but slightly toxic, and have a moderate and gentle action.

Hudelo has practised in the military ward of his clinic the following and expresses himself well satisfied with results.

With five days' interval he gives injections of novarsenobenzol of from 0.30 to 0.90 until he has injected a total of 4 to 5 grams; alternately with these he injects 0.01 of cyanide of mercury until he has given twenty doses. In some severe cases (intense cephalalgia, abnormal reaction from the medication, intense fever vomiting) he made a lumbar puncture and found the characteristic reaction; at the close of the treatment the serologic and spinal tests were normal and the patient appeared well. On all the discharge cards was noted the advice to recommence the treatment at the end of two months with mercury by pill or injections as might be possible.

Some method of combining mercury in the treatment with arsenic is recommended by Favre and Longin,[19] Pautrier,[20] Goubeau,[21] Pasteur and Mallein,[22] and Thibièrge.[23]

In private practice, where we can make our influence felt to a greater degree with the patient, we can pursue a course of after treatment following the indications in each case. If the Wassermann remains negative after six weeks to two months of repose, put the patient under the classical treatment by mercury, choosing by preference the soluble salts (benzoate, biniodide), giving a series of twenty injections followed by one month of repose, or ten injections per month for six consecutive months. If the Wassermann shows a tendency toward the positive when the patient presents himself after the period of repose following the first course of treatment, repeat the first course of forty days' mixed treatment and permit only three weeks to elapse before again submitting him to a serological test. If the lumbar puncture at the end of the first treatment gives an abnormal result (hypertension, albuminuria, lymphocytosis) the arsenic treatment alone or mixed with mercury should be given until these evidences return to normal and then the mixed or mercurial treatment should be inaugurated, but with not more than one month of repose between each cure. If the severe accidents appear (cephalalgia, cerebral obtrusion, vertigo, fever, nervous phenomenon), we agree with Ravaut and Hudelo that it is better to follow the lighter treatment by small dosage (0.05 to 0.15 of luargol and 0.01 to 0.015 of benzoate of mercury), extending over longer periods (10 to 15 injections of luargol in particular), repeating until these symptoms are brought under control.

After the patient has been brought to normal (Wassermann and lumbar negative), we still persist in following the classical treatment with mercury over a period of five years, making a Wassermann test at regular intervals to insure perfect control. Even with every known remedy and every precaution taken, we cannot be certain of a complete and permanent cure, and I do not believe we will arrive at a certainty of cure for this malady, which has been the curse of the human race since the dawn of history, until we have brought it under the influence of that magic cure for all diseases of microbic origin, syrum-therapy, if we ever arrive at a degree of knowledge that permits it.

MATERNAL IMPRESSIONS AND FEEBLE-MINDEDNESS.

By WILLIAM S. WALSH, M.D.,
WEST POWNAL, ME.
Assistant Physician, Maine School for Feeble-minded.

ANYONE who comes much into contact with the parents or relatives of the feeble-minded is certain to appreciate the widespread belief in maternal impressions. For example, he will be told that a certain child is epileptic because its mother, while pregnant, was frightened by a mad dog, or she saw someone in a convulsion; that another child is paralytic because its grandfather or someone else had a "stroke" in the mother's presence prior to the child's birth; that another child is feeble-minded because it was "marked" by a certain animal, a drunken man, a "simple" person who lived in the neighborhood, etc. Indeed, the various maternal impressions alleged to have caused mental and physical defects of all kinds might be quoted ad infinitum. It must not be supposed, however, that such reasons are given only by the unerudite; in fact, it is not at all hard to find clergymen, physicians, and others of the learned professions who assert their convictions as to the truth of maternal impressions as a cause of harm, and when those who are considered leaders and moulders of thought in their respective communities sponsor the doctrine, it is no wonder that it has such a tenacious hold upon people of all classes.

The belief in maternal impressions is as old as history. Evidences of it can be found among all peoples at all times. It is referred to in the Bible, also in the Laws of Lycurgus which commanded all Spartan wives to look only upon pictures and statues which exemplified the strong and the beautiful. And at various periods it has been attacked in books written in all languages. Though we believe our age to be a very intelligent one, this theory is still universally prevalent, and in the literature of the day we find it vouched for, sometimes by those whose opinions are considered authoritative.

The theory is no doubt founded upon the principle of the scapegoat.[1] From time immemorial man has striven to escape from that which would make him unhappy, and when obstacles to happiness presented themselves it was his wont to attempt to do away with them, as well as the responsibility for their appearance, by transferring the evil or sorrow to some person or thing, and by killing this person or thing he believed the impediment to his happiness was removed. If he could transfer a burden of wood or stones from his own back to that of another he reasoned he could likewise transfer pain, sorrow, disease, and evil of any kind to someone or something else. On this principle, animals were killed in times of plague; criminals or other human beings sacrificed for the sins of the community, or to keep it holy; and disease, by ceremony, transferred to animals or things and these done away with. The trial and punishment of individuals said to have caused evil by reason of witchcraft, the "evil eye," etc., and also the trial and punishment of animals and things, as during the Inquisition, relates to the same principle. And, no doubt, the effort to make animals or persons responsible for defective children follows the same lines. Or it may be considered part of the so-called projection mechanism, which, objectively at least, is founded on the principle of the scapegoat. Man's interests, and the community's interests, too, demand that his child be normal, but in the birth of a defective child an obstacle to happiness is encountered. It is an evil, a sorrow for which a culprit must be found even if in these times neither the evil nor the cause can be removed and forgotten. Man does not want to feel responsible for this evil; he feels, consciously or unconsciously, that he himself may be at fault, but such a thought would cause unhappiness. Hence he seeks some force that is working against his happiness, and to escape responsibility he makes a scapegoat out of someone or something. Or we may say he projects his difficulty upon someone or something and punishes it by his hate. The mechanism represents the age-old effort to escape the unhappy, to throw burdens and difficulties, due often to self-deficiencies, upon something else, and in doing so shifting the responsibility, and thus escaping unhappiness. And how people seek to escape personal responsibility for their defective offspring is shown by their hiding ancestral taint; in the husband, blaming the wife, and vice versa; in blaming animals, or persons, for the evil. Moreover, those who know the fallacy of the doctrine of maternal impressions are loath to disbelieve it. They realize that it is possible for a defective child to be born to them and in such a case the interpretation that the public may have upon it, even though the child's condition is due solely to extrahereditary causes. In maternal impressions they have a cause, a means of transferring possible responsibility, an object upon which to vent their hate, and, last but not least, an explanation believed by the curious.

The theory of maternal impressions contends that a vivid impression or emotion of some kind experienced by the mother can in some mysterious way produce a structural change in the unborn child corresponding to the maternal impression. For example, fright occasioned by a rabbit may cause harelip in the child; fright from fire, the sight of blood, an unsatisfied craving for cherries, tomatoes, etc., or the mother's touching herself while frightened may result in nevi or so-called strawberry marks. According to some, even reading a book that is unpleasant, or harboring an unpleasant thought may affect the child in some specific manner. The theory also assumes that it is possible for the mother to have her child a genius or anything she desires, simply by willing such. Also, it espouses the belief in the direct transmission to the child of mutilations experienced or witnessed by the mother.

Without doubt severe emotional states experi-

enced by a pregnant woman, or unpleasant emotions continued over long periods, may have a detrimental influence upon the fetus. However, if they act, they do so by interfering with the nutrition of the fetus, either by rendering the mother's blood poor in quality or quantity, or by rendering it poisonous. The emotions, we know, excite many of the ductless glands, causing them to liberate large quantities of material which, in large amounts, act as poisons; the emotions also upset normal metabolism. Werber,[2] by selecting injurious substances known to arise during faulty metabolism in the human being, as butyric acid, and acetone was able to produce deformities such as cyclopia, defects of the ears or eyes, hydrocephalus, etc., in the offspring of the marine teleost fish, *Fundulus hetcroclitus*. Of course, it is possible that such poisons may be produced in large amounts as a result of continued emotional states, but it is as yet unwarranted to assume that such explain human developmental anomalies. Granting that the emotions may affect the fetus detrimentally such an effect would be general and not specific; that is, the structural change or changes in the child would not correspond to the particular emotion of the mother nor its cause. As a general thing, in practically all cases where fright is the alleged cause of the "mark" the fright was so slight as to cause scarcely more than transient thought at the time; indeed, it was quickly forgotten, to be resurrected, after much thought often, subsequent to the child's birth. We should remember, too, that a pregnant woman can apparently experience much emotional shock without detriment to the child; if harm is done it usually results in death of the fetus. The report of Baron Percy is often quoted to show the apparent influence of fright upon the pregnant woman. According to him, of 92 children whose mothers had been exposed to the cannonade at Landau in 1793, 16 died at the instant of birth, 33 died between the eighth and tenth months, 8 became idiotic and died before the age of five years, and 2 were born with numerous fractures of the ribs. However, Pestalozzi and Resnevic some time ago respectively reported on 40 and 20 women brought to the Rome maternities from the earthquake district. All of these women had undergone the terrors of the last Italian earthquake, and many had been buried under the ruins for hours. But two gave birth to premature children; the remainder gave birth to living, normal babies.

The impossibility of a specific maternal impression having a specific effect upon the unborn child should be apparent to anyone at all familiar with physiology. The only connecting link between mother and fetus is the umbilical cord which has no nerves. The only means of communication between the two is the blood and the mother's blood does not directly pass to the child, being first deposited in the placental blood spaces. That the blood cannot carry impressions should be conceded without question.

Negative evidence alone should be sufficient to disprove the theory. Quoting Pohlman[3] Bischoff in 11,000 confinements was unable to find a single case of maternal impression, and William Hunter says that for many years all the women who entered a large maternity hospital in London were asked if anything had especially affected their minds. If so the answer was written down. In no case where an abnormality was noted on birth of a child could a relationship be traced to its mother's recorded answers though the women frequently suggested a cause when they learned the nature of the abnormality. Again, we see day in and day out anomalies of development in the vegetable and animal kingdoms without attributing such to maternal influences; and if there were anything in the theory monstrosities should be the rule and not the exception, considering how impossible it is for a woman to go through a pregnancy without being impressed by some unpleasant emotion. And thousands upon thousands of mothers, who feared their children would be "marked," have found, as is the case with most worries, that they concerned themselves unduly over things that did not happen.

Doubtless, it will not be hard for believers in the theory to find some cases that apparently support their belief. But as a rule such oft quoted, stock examples as have been thoroughly investigated have been disproved, and the real etiological factor traced to something more in accord with science. A great many of the stock examples are as old as the hills and are not open to investigation; they have been accepted on the mere say so of someone and have been recorded in the literature without verification, and we must remember that errors not infrequently creep into medical books and journals which are considered authoritative. Human beings are gullible; moreover they delight in the mysterious and have a love for that which appears dramatic, and considering the number of coincidences which happen daily it is nothing remarkable if an occasional case, which apparently supports the theory, occurs.

It is probably in connection with the feeble-minded that the theory of maternal impressions is most used. Some time ago the writer went over some 300 cases of definite feeble-mindedness in the preparation of some statistics. The frequency with which the parents or relatives ascribed the mental defect to maternal impressions was truly noteworthy. "Marked by a horse, a hurricane; mother frightened by a drunken man; mother fondled a feeble-minded boy," etc., were but a few of the many reasons given. Yet in all but one of these cases, and in this one case the history was not complete, the true cause of the deficiency could be found in a tainted heredity or other causes recognized generally in the etiology of feeble-mindedness. For example, one epileptic idiot was said to have been "marked" by a seal. The family history of the patient shows that some of his maternal relatives are mentally defective, his father is feeble-minded and an alleged luetic, his mother is feeble-minded and epileptic, his sister feeble-minded and epileptic. Surely such an ancestry is enough to explain his condition. It is now well recognized that from 60 to 80 per cent. of all cases of feeble-mindedness can be traced to a morbid heredity; the remaining cases to injury at birth, disease in early life, etc. If

one looks up various text books on feeble-mindedness he will, of course, find a certain number of the cases, from two to five per cent., alleged to be due to disturbed mental states in the mother. However, the writer has always felt that such statements are unsatisfactory, and are used often when, owing to an incomplete or unreliable history, there appears nothing else to explain the defect. Mongolism, which comprises about three per cent. of the feeble-minded, is often ascribed to emotional states of the mother, but we must confess that its real etiology is unknown. At any rate, it is preposterous to believe that it may be caused by a mother being frightened by a Chinaman. When we face the facts we must admit that in the etiology of feeble-mindedness maternal impressions play no part; if we were to believe interested persons they would explain at least 50 per cent. of all defectives whether mental or physical.

Of the impressions alleged to cause mental defect "marking" by animals is most common, and if we were to study a group of low grade defectives we would surely find many who betrayed characteristics more or less peculiar to animals. The brothers Ceretti, the Bird Man, the Rabbit Man, and others described by Lombroso can easily be duplicated in any institution for the feeble-minded. The writer has encountered many of these children said to resemble some animal but it has been his experience that in none of these cases have the parents noted the fancied resemblance; usually they ascribed the cause to something other than fright by an animal. In other cases where fright caused by an animal was the alleged cause, no resemblance could be found to the animal mentioned. In all the cases the true cause could be found among the recognized causes of mental deficiency. The fact that some low grade defectives may bark like dogs, chirp like birds, neigh like horses, crow like roosters, etc., and betray actions said to resemble those of a certain animal is not at all peculiar. Low grade defectives are physically deformed and they act in atavistic fashion simply because they are idiots or low imbeciles, to which such peculiarities are common. As a rule, the alleged resemblance to a certain animal is much overdrawn and would not be noticed if someone of a fanicful turn of mind had not pointed it out.

Should an illegitimate child be feeble-minded there are those who believe that the illegitimacy is, *per se*, sufficient explanation; if they are of a strongly religious turn of mind, the defect is attributed to the wrath of God; the worldly minded may ascribe it to the experience of shame and sorrow the unwedded mother is supposed to go through. The fact that a child is unwanted, whether the mother be married or single, has been cited as a cause of the so-called epileptic constitution. However, the principal fact determining whether or not an illegitimate child, or any other child for that matter, will be born normal mentally and physically is the quality of the germ cells that go to form its make-up. If these cells are normal the illegitimate child has as many chances of being born normal as a child born in wedlock. Many illegitimates have made their niches in the halls of fame, as reference to Lombroso's "Man of Genius" will attest. We should bear in mind, however, that it is feeble-minded girls who are the mothers of a large percentage of illegitimates. It is generally accepted that at least 50 per cent. of prostitutes, street walkers, and others of similar ilk are mentally defective; others are epileptic, psychopathic, or diseased physically; the latter not alluding to sex disease from which all prostitutes suffer. Many of these persons living unchastely have, at one time or other, borne one or more illegitimate children. As a general thing, if one parent is normal and the other defective, the children are due to be apparently normal, though carriers of defective germ cells. However, the fathers of these girls' children are often feeble-minded, psychopathic, or otherwise unstable on an hereditary basis, in which case the child, receiving a double inheritance of defect, can hardly be normal. A tree is usually known by its fruit, and if a certain percentage of illegitimates are abnormal the probabilities are that such is an expression of morbid heredity, rather than a token of divine wrath or extra-hereditary maternal influence. Should such children prove immoral or otherwise anti-social they did not inherit these tendencies as such; they inherited abnormal nervous structures, the anti-social acts being merely symptoms of such. Even though the illegitimate proceed from normal parents it is only natural for it to become an enemy of society if, as is often the case, it develops in a poor environment. A good heredity gives a child the material upon which a good character may be built; it is training and environment, however, which moulds the character; and considering the many hardships society unjustly imposes upon the illegitimate, it is no wonder if it chooses, or is forced by chance or circumstances, to live at odds with society.

It is believed, too, that a child conceived while one or both parents were drunk is apt to be feeble-minded, or to show physical peculiarities, as a reeling gait. Some attribute this to the disgust and horror the drunken person excites in the other. It is also attributed to poisoning of the germ cells by alcohol. The influence of alcohol as a "racial poison" has been a matter of much dispute. Stockard's experiments, showing that alcohol caused various abnormalities in the progeny of guinea pigs, have been widely quoted. However, his views are by no means accepted by all. The experiments of Nice' are worthy of being read in this connection; briefly it may be said that Nice administered alcohol in the food and by inhalation to white mice without any appreciable effect as regards fertility, vigor of growth, and viability. Again, the results of experiments performed upon sensitive animals, as guinea pigs, hardly justify sweeping conclusions relative to their applicability to man. For example, liquid petrolatum will cure scurvy in guinea pigs but not so in infants. Instead of looking upon excessive drinking as the real cause of so much mental disease and defect it is more worthy of being considered an expression of some pathological condition. Drunkenness is often a symptom of insanity, feeble-mindedness, the neuroses; and many people drink excessively because they are nerv-

ously unstable rather than unstable because of drink. If the child of a drunkard is mentally defective, in place of blaming alcohol the real facts responsible for the drunkenness should be considered; if so, the defect will probably be a matter of heredity.

Sometimes because the child of a drunkard becomes a drink addict in later life some people conclude that the taste for drink was inherited; even that the sight of the drunken husband so influenced the mother as to "mark" her unborn child in this specific manner. There is a form of periodic drinking, apparently related to the epilepsies, which tends to act in an hereditary fashion, but it may be accepted that a specific taste for alcohol is not inherited. If the child of a drunkard is abnormal mentally it may take to drinking later in life simply to escape temporarily, at least, the various difficulties bound to arise as a result of the abnormal mental condition. In such a case the drinking is a sign that something is wrong. To-day we are getting away from the idea that drunkenness is largely a matter of habit; instead, there is more reason to believe that drunkards are drunkards because they find drink a means of escape from trials or problems with which they cannot adjust themselves. Just as the man who loses his position, who suffers a bereavement, etc., goes on a spree because he is unable to adapt himself to the new situation, so also do chronic drunkards, or the majority of them, at least, take to drink because they are unable to adjust themselves to the world of reality. Of course such is an abnormal condition, for the normal person is able to face the difficulties which threaten his happiness. If the child of a drunkard is born normal, family habit or environment or the development of a neurosis or other disease which does not permit of self-adjustment to difficulties will usually explain the drinking habits, if any. As most of us must have noticed, many of the children of drunkards are not only total abstainers, but are also normal mentally and physically; again, the children of races that drink hard routinely or at certain festive seasons are not conspicuous for mental or physical defect; that in both cases many of these children were conceived while one or both parents were drunk seems probable, thus weakening the case of maternal impressions. The occasional birth of a child which from the age of walking, or later, shows a gait somewhat like that of a drunken man is not at all sufficient to support the view that it was "marked" by a drunken father. No doubt many of the cases attributed to the latter cause were due to Friedreich's ataxia of which the reeling or drunken gait is typical. It is a family disease and sets in early in life. In Griffith's 143 cases, alcoholism was noted in only 7 cases, so that alcohol appears to play no particular part in the etiology.

Just as a tainted heredity will account for a large portion of mental deficiency alleged to be due to maternal impressions, so also will it account for many crass physical defects attributed to the same cause. There are any number of physical defects which act in an hereditary manner, as polydactylism, hypophalangism, acephalus, defects of the eyes, ears, etc. The real part heredity plays in causing these defects is often not appreciated. The average physician makes but a very perfunctory inquiry into the family history of his patient; again he hesitates to inquire deeply lest he cause offense. If the patient knows of familial deficiency, the tendency is to hide it; also, few people have much worth-while knowledge concerning their ancestors. An important point, too, is that hereditary defects sometimes skip a generation and so are apt to be forgotten as existing in the family line. The difficulty in tracing anomalies attributable to heredity is also added to when the characters act as recessives, and when, occurring in miscarriages or still births, they escape notice.

The impossibility of moulding the fetus into a genius or other desirable superior being simply by the mother's will-power is evident. Practically every expectant mother spends the days of waiting wishing great things for her unborn one, and how many times is she grievously disappointed! If there were anything in the theory the woman who sighs for a boy baby should not be disappointed so often by the birth of a girl.

If the mutilations were directly transmissible the children of cripples and others physically misfit through accident or circumstance should be likewise defective, yet we know that such is far from being the case. If a child is born with a digit or more missing, in place of its being due to the mother seeing a crushed finger or the like, the chances are that it is a case of hypophalangism which is hereditary and which, furthermore, may skip a generation. And if a child is born a paralytic there are any number of birth accidents to explain it rather than a maternal impression of some kind. As illustrating the apparent transmissibility of mutilations Prof. Häckel's instance of the bull which having had its tail squeezed off by a byre door subsequently produced tailless calves is often quoted. Another instance is that of a cow said to have produced hornless calves after losing her own horns through disease. Just what the real explanation of these cases is I do not know, but any number of animals lose portions of their physical members and have healthy progeny. As offsetting the examples quoted, the following is interesting: Last year we dehornated some 30 cows. At the time 12 were pregnant. All gave birth to healthy calves which to this day show no peculiarities of the horns.

Of course we will at times find anomalies of development which apparently defy explanation. But before falling back on maternal impressions we have more scientific theories to bring forth. For instance, in 1908 Mall,[5] from a study of pathological human embryos, concluded that defective prenatal development was due to faulty implantation of the ovum in the wall of the womb. This faulty implantation might be brought about by any diseased condition of the womb. When such implantation occurs the nutrition of the ovum is interfered with and this leads to its death or to a monstrosity. Diseases of the chorion, the placenta, are known to be associated with defective children; and toxemias may play a no small part. Lues apparently does not; Holt found the Wassermann negative in 56 children born with various

congenital abnormalities. Whatever the cause, in no instance open to investigation can a case be made out in favor of maternal impressions.

The theory of maternal impressions does no real good and causes much suffering. For one thing, it prevents people from realizing their hereditary defects, if any, and thus they feel free to marry and salve their consciences on the birth of a defective by making a scapegoat out of some animal, person, or thing. Moreover, the unfortunate offspring is denied the care and training it should have from its earliest years; it is a "marked" child and therefore not like other defectives on an hereditary basis. Again, countless women torture themselves throughout the days of their pregnancy, fearful lest some emotional experience, some abnormality they have seen, or even read about will, in some way, "mark" their children. Physicians and others in a position to do so should in every way possible combat the theory. It is not prenatal culture and the like that our future men and women need but prenatal care; if they have this, and if parents realize the right of every child to be well-born, the appalling death rate among infants and the number of defectives of all kinds will materially lessen.

From this article it is hoped that it will not be assumed that the writer is attempting to account for all sorts of deficiencies by a tainted heredity. Without doubt, heredity plays no small part in their causation, and a part more real than the average person supposes. However, while heredity will explain many abnormalities, many of the latter are also due to chance happenings which might occur in families of the purest stock. A defective child in a family is not, *per se*, a trustworthy sign that the whole family is tainted, yet many embryo students of heredity and social problems are not loath so to condemn it, thus causing lasting and irreparable harm often. They do so by reason of hasty generalization, without taking the trouble to seek out the facts; if they sought out the latter they would often find that the family they condemned showed evidences of being of infinitely more value to the community, present and future, than the amateur eugenicists. The question of heredity is a complex one, and only those fully acquainted with its various ramifications and apparent contradictions should presume to draw conclusions in any given case, and then only after a thorough investigation of the facts. Nor should we be led astray by the theories of those we consider authorities; as Lyon says: "Authority is useful as a factor in critical judgment; it is fatal as an object of worship." Heredity tells us what has happened in the past and what may happen in the future; but he who, because a certain point has been worked out in the animal or vegetable kingdom, presumes to say just what will happen as the result of any given mating, is apt to err. Bad trees sometimes bear good fruit. The author's contention is this: The belief in maternal impressions as commonly accepted has no scientific basis on which to rest, and along with many other archaic theories pertaining to the realm of medicine deserves a place in the waste basket. So far no one has made out a good case for it, and, in the light of our present knowledge, it is doubtful if anyone ever will.

ON PAROTITIS AS A COMPLICATION OF INFLUENZA.

By DAVID I. MACHT, M.D.,

BALTIMORE.

WHILE an acute parotitis is not an uncommon complication in a number of infectious diseases, such as typhoid fever, etc., an inflammation of the parotid gland as a complication or sequel of influenza is of extremely rare occurrence. Osler in his "System" quotes twelve cases from the German army statistics. These are described more in detail by Leichtenstern in Nothnagel's "Handbuch" (Bd. IV, H. I. S. 147). That author mentions the sporadic occurrence of a parotitis in the influenza epidemics of 1580, 1732, and 1734 and further states that among the carefully studied 55,263 cases in German army statistics only *twelve* such cases were found. The present author has had the good fortune of studying a case of influenza parotitis which, owing to the great rarity of the condition, he deems worthy of reporting.

Mr. N. S., white, twenty-four years old, was attacked by influenza on October 4, 1918. The disease in this case was of an extremely severe character, with high fever (104°), marked prostration, and collapse symptoms. A few days after onset the patient developed a bronchopneumonia, chiefly localized in the right lung. The pneumonia lasted for two weeks, when the patient gradually began to improve and the fever disappeared.

At the beginning of the third week in the course of the disease the patient was suddenly taken with a pain in the right parotid region, a definite swelling was noted, and the patient could hardly open his mouth. It was at first thought that he was getting the mumps, but the subsequent course of the disease showed that that was not the case. The parotitis did not develop on the other side, but was confined to the right parotid gland. Instead of subsiding after a few days, the swelling increased and the symptoms became aggravated, requiring the use of opiates. A fever of 100° to 101° F. was noted. The patient was examined by Dr. Richard Follis, surgeon, in order to determine whether an abscess was forming, but no abscess formation was found. The parotitis persisted without softening of the gland for two weeks. After that period it began gradually to subside. A definite swelling and hardness of the parotid gland, however, was noted as late as three weeks after the onset of the complication. The patient finally made a complete recovery.

Physical examination of the chest and abdomen and analysis of the urine showed nothing remarkable.

3218 AUCHENTOROLY TERRACE.

Pathogeny and Treatment of Cancer.—Cisneros recommends electroignition, which he has employed in cancer for eighteen years. He leaves the lesion open and proceeds against it at the first intimation of recurrence. Electrical methods may be used also as adjuncts to the knife and one may look forward to 100 per cent. of cures in operable cases along with a considerable percentage in inoperable cases.—*Semana Medica.*

Medicolegal Notes.

Workmen's Compensation Acts—Does "Surgical Aid" Include Artificial Limbs, Etc.?—The Connecticut Workmen's Compensation Act requires an employer to furnish such surgical aid to an injured employee as the attending physician or surgeon shall deem reasonable or necessary. The question is raised whether surgical aid or service includes the furnishing of crutches, artificial legs, artificial eyes, etc. The Connecticut act merely uses the general term "surgical aid," differing in this respect from the New York act, in which there is a specification of various things to be furnished. The Connecticut Supreme Court of Errors is of opinion that the Legislature, in using the general term, intended to include all things that might reasonably fall within its provisions. It is part of the duty of the surgeon, the court said, to prepare the stump of arm or leg for the artificial leg or arm. It is a part of his duty to adjust it. Why give the patient splints to hold the bones in place or crutches with which to walk and regard these as used in surgery? Why supply a glass eye? Because it is the everyday duty of the surgeon to order these things for his patient, and they are included as of course under "surgical aid." There is no difference in principle between supplying these and the artificial limb. That pertains to surgery and is used in surgery. The stump must be prepared by the surgeon to receive the artificial limb, and that must be adjusted to the stump by the surgeon. The only difference between the crutch and the artificial limb is that the latter costs more than the former.

The purpose of the provision in question is to restore the injured employee to a place in our industrial life as soon as possible by the use of all medical and surgical aid and hospital service which the ordinary usages of the modern science of medicine and surgery furnish. Humanity and economic necessity in this instance are in harmony in working for the accomplishment of the individual and of the public welfare. "Surgical aid" is a term of technical significance and has an established meaning in standard works on surgery. The duty of the surgeon does not end with the healing of the stump. "As soon as all sensitiveness has left the end of the bone, an artificial limb should be fitted and the patient urged to make efforts to use the extremity."—Keen's Surgery, Vol. V, p. 951. The duty of the surgeon continues until the artificial limb is adjusted and the patient has learned how, with the help of the surgeon, to use it properly. It would not be questioned that the entire bill of the surgeon for his services would fall under the head "Surgical Aid." It would be difficult to justify this expenditure, as well as that for bandages or ointments or other material used by the surgeon in his treatment of the patient, and not make a like expenditure for the artificial leg in connection with which these things were used.

Prentice, C. J., dissented because he thought the provision of artificial limbs for the improvement of physical efficiency, following such repair of the consequences of injuries received as the circumstances will permit, lies outside the sphere of the surgeon's professional activities as that sphere is commonly understood and established by actual practice.—Olmstead v. Lamphier, (Conn.) 104 Atl. 488.

Quarantine of Contagious Diseases — Delegated Powers of Boards of Health.—The Washington Supreme Court holds that though article 20, section 1, of the state Constitution provides that a state board of health shall be created, and makes no provision for the establishment of city boards of health, a city has general power by statute and at common law to enact necessary police regulations for preservation of the morals and health of the inhabitants, as to pass health ordinances or create the office of health commissioners, except as limited by contrary provision of the general law. It is held that ordinance of Seattle No. 15957, as amended by No. 32444, providing for the detention and quarantine of persons afflicted with contagious and infectious diseases, is not in conflict with the general law or the statutes creating the state board of health; the sole power in the state board being satisfied by the preservation of the right of appeal to that board. The ordinances and the statute creating the state board of health and rendering final its decision in matters of quarantine are legitimate exercises of the police power of the state, as founded in sound reason. It also holds that the act of the state board of health in determining whether or not a given person is afflicted with contagious, dangerous, or infectious disease is in no sense judicial, and the Legislature could provide for taking the judgment of persons skilled in disease as final on the question, without review by the courts. The questions grew out of the commitment to the isolation hospital of the city of Seattle of one found by the health commissioner of the city to be afflicted with syphilis.

One of the defendant's contentions, on appeal, was that the law is unconstitutional, in that it delegates legislative power to the health boards, since it leaves to them definitions and classifications of diseases. The court said that it has not heretofore considered similar laws as a delegation of legislative power or authority. The legislation is that of the legislative body, but it is not always practical to meet every phase of the necessity that has called for the law by the enactment of a general statute. The Legislature may well have taken notice of the fact that the nature, virulence and extent of territory covered by contagious and infectious diseases, whether endemic or epidemic, are all factors to be considered in the matter of quarantine, and that, after all, the whole working of a plan for quarantine must depend upon the judgment and discretion of men learned in the science of medicine, and that doctors often disagree. The Legislature, as well as the courts, would be helpless in such matters without resort to expert opinion, and their judgments would necessarily lie in greater or less degree in the facility of witnesses and the skill of counsel. It is most likely that the Legislature sought to avoid the confusions and delays that must necessarily follow if arbitrary classifications were attempted in the statute, for if it had the power to say, in emergency (in self-defense), that, inasmuch as the whole matter of quarantine must rest ultimately in the judgment of medical men, it would avoid the danger of partisan opinion and fix the seat of that judgment in men of its own choosing, or to be chosen in a way provided, and who being bound by oath to perform a public duty, and having a due sense of responsibility, presumably would discharge their office with justice and fidelity. The court thought there was no legal reason for denying the power to quarantine summarily.

It is settled that laws and ordinances creating boards of health and granting wide powers for the effective and effectual carrying out of the legislative plan for protecting health must be liberally construed. This being the rule, the power of the legislative branch of the government is not to be lightly interfered with or set aside. Courts will not seek for an opportunity to declare a right of appeal or review in cases resting in public necessity. In a similar case the Supreme Court of New Jersey said: "But upon the general merits of the controversy we are unable to perceive anything in the legislation referred to conferring upon the common pleas the right to review the conditions and the emergency in the locality which prompted the board of health to impose the restrictions and quarantine complained of in this case. We are unable to perceive any authority in the legislation itself, or in the public policy upon which it is based, which can be said to contemplate the submission to a legal tribunal of the public necessity, which requires in an emergency the prompt and expeditious intervention of a board to which the Legislature for the protection of life and health in a community has especially committed the determination of the facts." Board of Health v. Court of Common Pleas, 83 N. J. Law 392, 85 Atl. 217—for, as said in that case, to assume to review a finding of a properly constituted officer vested with authority to determine a fact in a critical situation involving detriment to the life and health of a community is tantamount to a declaration that the police power of the city is moribund and useless.

Finally, the court held that it is within the power of the Legislature, in dealing with the problems of public health, to make the determination of a fact by a properly constituted health officer final and binding upon the public as well as upon the courts.—State v. Superior Court, Washington Supreme Court, 174 Pac. 973.

Military Medicine.

The Solar Dressing for Wounds.—Pierra applies this term to the heliotherapy of wounds. He considers especially the local application of the solar rays, leaving sun baths, which combine free air with light and warmth, for other writers. In the solar dressing the rays exert a direct sterilizing influence on the wound surface, and moreover hasten cicatrization. The author has closely studied the action of the rays on wound healing under suitable control. He selected atonic and especially trophic lesions such as result in part from a mechanical factor, including freezes and varicose ulcers. In these torpid lesions there is no lymphorrhea, no epidermization. The rays cause first in such wounds a hyperemia which should in turn give rise to pigmentation. The latter signifies that vitality in the cells has been awakened, and with it the reparative process. Edema and lymphorrhagia may also be seen and this means that the wound is draining and cleansing itself. By taking a large number of torpid wounds of various kinds and timing them under the influence of the solar rays, he satisfied himself that healing nearly always occurred and within a relatively short time. The number of hours of exposure added up from 12 to 142 and the number of séances from 5 to 45. So much for the power of cicatrizing old and torpid wounds. The author, however, finds another indication for the rays, to wit, in the sterilization of recent infected wounds. These must of course, be accessible, for deep wounds with pockets cannot be reached by the rays. The bactericidal power is greater over anaerobes than over aerobes. It is hardly correct to speak of a bactericidal action for it is really one of mere inhibition on germ activities. The results are more inconstant than in torpid lesions and the figures quoted seem to show that the sun does not compete with other standard methods in this class of wounds, but might be of much use in the absence of the surgeon's ordinary equipment and as an accessory. The author confesses that by itself the sun would hardly answer here, but as an accessory it is of value even in bone and joint surgery. —*Journal de médecine et de chirurgie pratiques*, October 25, 1918.

Influenza Decreases in Camps.—A report from the War Department, on December 20, states that although influenza is still prevalent in all the army camps there has been a decline in the number of cases for the week ended December 13 as compared with the preceding week. The total number of cases was 3,830, a decrease of 426 over the preceding week.

Hospital Construction Approved.—The plans of the Public Health Service for hospital construction costing $1,000,000 have been approved by Congress.

Will Aid Blind Soldiers.—Sir C. Arthur Pearson, head of the British National Institute, devoted to the care of men who have lost their sight in the war, and himself blind, sailed for this country on December 20. The object of his journey is to confer with those who are responsible for the care of American soldiers blinded in the war and with Canadian authorities regarding the future welfare of Canadian soldiers trained at St. Dunstan's Hostel for Blinded Soldiers and Sailors in Regent's Park, London.

Oregon Soldiers Make Record.—The records of the Surgeon General's office show that of all Oregon's enlisted and drafted men only one-half of one per cent. have been found suffering from venereal disease. Oregon is said to have the honor record of the war in this respect.

Maj. John M. Berry, former epidemiologist in the New York State Department of Health, has recently been promoted to the rank of Lieutenant-Colonel.

Deaths in the Service.—Lieut. Thomas Jefferson Palmer, M. C., U. S. Army, of McAlester, Okla., a graduate of the University of Illinois, Chicago, in 1905, was gassed while on duty in French Hospital on the western front, September 10, and died October 28, at Base Hospital No. 14, Bordeaux, France, at the age of 39 years.

Assistant Surgeon Bertram L. Cunningham, lieutenant U. S. N. R. F., of Jamaica, N. Y., a graduate of the New York Homeopathic Medical College, in 1913, on duty at the Medical Office, Third Naval District Headquarters, New York City, died on October 21 from bronchopneumonia, aged 30 years.

Lieut. Samuel Dennison Shannon, M. C., U. S. Army, of Baltimore, a graduate of the University of Maryland, Baltimore, in 1915, in the British medical service, died from influenza in the Red Cross Hospital, London, on November 5, aged 26 years.

Capt. James McFarland, M. C., U. S. Army, of Burlington, N. J., a graduate of the University of Pennsylvania in 1911, aged 31 years, died in France on October 24 from wounds received in action.

Lieut. Frederick George Carow, M. C., U. S. Army, of Brooklyn, N. Y., a graduate of Jefferson Medical College, in 1917, aged 30 years, died from pneumonia while on duty at Camp Upton, N. Y., on October 16.

Lieut. LeCount Rochambeau-Lovellette, M. C., U. S. Army, of Chicago, a graduate of the University of Illinois, in 1917, died from lobar pneumonia while on duty at Fort Sam Houston, Texas, on December 2, aged 25 years.

Lieut. Albert Fabian Welin, M. C., U. S. Army, of Rio Vista, Cal., a graduate of Leland Stanford, Jr., University, Palo Alto and San Francisco, in 1915, died from pneumonia following influenza, at Camp Kearney, Cal., on October 31, aged 28 years.

Capt. Pleas Daniel Barnhill, M. C., U. S. Army, of Brenham, Texas, a graduate of the University of Texas, in 1876, died from arteriosclerosis on October 26, aged 52 years.

First Lieut. Clarence Macomber, M. C., U. S. Army, attached to the base hospital at Aviation Field No. 4, Garden City, L. I., was instantly killed in the main street of the camp on December 20, when a team of runaway mules crashed into an ambulance. Lieutenant Macomber was 40 years of age, and came from New Charon, Me.

Lieutenant Donald G. Russell, M. C., U. S. Army, of New Haven, Conn., a graduate of Yale University Medical School, in 1914, died of disease recently while on duty in France, at the age of 28 years. He had served in the Medical Corps since shortly after the United States entered the war.

THE RELATION OF INCOME TO SICKNESS.

ECONOMIC conditions have a great deal to do with the incidence of sickness, but whether this depends upon inferior diet chiefly, upon unsanitary modes of life, or upon a concatenation of these circumstances, has not been made quite clear. In the case of pellagra it appears to have been shown in a sufficiently convincing manner that diet is a preponderating factor in the causation of this disease. With regard to rickets, evidence goes to show that unsanitary conditions in the home are, at any rate, contributory causes of the disease, but opinions differ as to the rôle played by diet.

Recently, Drs. G. A. Wheeler and Joseph Goldberger of the U. S. Public Service and Edgar Sydenstricker, public health statistician, have published in Public Health Reports, September 22, 1918, the outcome on some investigations into the economic conditions prevailing among a population of seven cotton-mill villages of South Carolina and the effects of these conditions upon the health of this community. The authors state that while extreme caution should be exercised in drawing broad conclusions from the small amount of data which they have been able to gather as the result of their investigations, the experience derived from the census of sickness and from the records of working days lost on account of sickness in the seven cotton-mill villages studied appears to suggest the following: (1) A higher sickness rate, involving inability to work, and a greater amount of working time lost on account of such sickness were found among members of families whose incomes were low than among members of families with a more favorable economic status. This condition appeared for persons of either sex and of similar ages. Only when a family income approximated $10 per half month per adult male unit, or about $900 a year for a family of normal size in 1916, did the sickness rate appear to be as low as that suggested by similar censuses in a number of localities in the United States as the normal rate. (2) Low economic status appeared to be a more striking concomitant of high sickness rate than employment in mill work. (3) A greater proportion of disabling sickness, of relatively long duration, appeared among persons whose family income was below the average than among persons with a more favorable economic status. The data collected and analyzed by the authors are too incomplete to warrant the making of dogmatic statements or of drawing definite conclusions therefrom. However, the data do suggest, from the fact that where the income was very small disabling sickness was prevalent, that there is a relationship between low economic status and ill health. This view seems to be corroborated by previous observations and recent investigations. The lowest paid and the least regular workers are the worst nourished and the most prone to disease. As the authors say, the data presented by them afford additional ground for the suggestion that in the analysis of morbidity facts the factor of economic status should be given due emphasis.

THE CAUSATION OF RICKETS.

THE causation of rickets is still a moot point. In spite of the fact that several authorities on children's diseases in this country and in Europe have pointed to dietetic deficiency as a main etiological factor, this view is by no means unanimous. There is one feature of the situation, however, on which all are agreed—that children most liable to rickets are those who live under unsanitary conditions, and the statement applies more especially to the condition of the home itself than to that of the district. There is much to be said for the argument that rickets is essentially a food deficiency disease, but it has not been proved conclusively to be so.

The British Medical Research Committee has published recently "A Study of the Social and Economic Factors in the Causation of Rickets," based on work carried out in Glasgow by Miss Margaret Ferguson under the direction of Prof. Noël Paton and Dr. Leonard Findlay. The subject of rickets was thoroughly investigated from social, economic, and dietetic points of view in families containing rachitic children, in families of the same social scale in which no rickety children were discovered, and also in a proportion of families resident in garden cities.

Twenty-five conclusions were reached, the most interesting being those dealing with the question of diet. It was found that the duration of breast feeding seemed to have no relationship to the incidence of the disease. That the majority of cases of both rachitic and non-rachitic children seemed to have had an adequate supply of fat during infancy. That the age at which artificial feeding was commenced seemed to be of little moment. That the diets of the rachitic and non-rachitic families showed no significant difference in energy value or protein content. That while the amount of fat in the diets of non-rachitic families was on the average 10.7 per cent. higher than in those of the rachitic, the overlap was so great that a defective supply of fat could not be considered as playing an essential part in the causation of rickets, and the evidence was against a deficiency of milk, of butter, or of the fat-soluble A substance being a determining factor. On the other hand, it was

decided that inadequate ventilation and deficient exercise were potent etiological factors.

In the opinion of the investigators the condition of the house had much to do with the causation and development of the disease. Overcrowding, vitiated air, and lack of cleanliness in the house, favored the production of rickets, and by improving the housing conditions the disappearance of the disease would be brought about.

These findings are interesting, though, of course, not in any respect final. They appear to minimize somewhat unduly the effects of dietetic deficiency in the causation of rickets. Good air and exercise tend, no doubt, to prevent rickets, but a sufficiency of suitable food would seem to be an etiological factor of at least as great importance. The evidence in favor of diet being closely concerned with the causation and development of rickets is quite as strong as that which attributes the condition to unsanitary surroundings.

NONSPIROCHETIC EPIDEMIC ICTERUS.

That in times of war and general distress a form of epidemic icterus, which is not a benign type of spirochetosis icterohemorrhagica, may occur, is well shown by an account by Professor Cantacuzene in *La Presse Médicale* for Oct. 24 of an epidemic in Rumania. This occurred in the autumn of 1917, beginning in the latter part of August and attained its maximum at the first of October. It did not become entirely extinct until the expiration of another six months. It was originally limited to troops but eventually became a civilian disease. The major features were extreme diffusibility, absolute benignity, and constancy and simplicity of clinical picture. Many Rumanian contributions on the epidemic were published. Other forms of jaundice encountered at the same time could readily be excluded, such as icteric recurrent fever, icteric typhoid, and the like. The disease first appeared in isolated foci but soon spread in waves. Hundreds of soldiers presented subicteric tinge of the conjunctiva, often so slight as to escape the subjects' own observation. In some cases there were gastroenteric symptoms. The contagiousness is well shown by the fact that a soldier on leave of absence immediately conveyed the disease to the members of his family, whence it soon spread among the neighbors. An infected soldier who lodged with seven others spread the disease so rapidly that in a few days all were infected. As to the exact mode of transmission nothing has been proved. Lice and mosquitos can readily be excluded as carriers. There is evidence to show that healthy human carriers can spread the infection.

The subjects were apparently non-febrile, but the thermometer and the complaint of slight chilliness showed a subfebrile temperature. After this period some men complained of nausea or diarrhea. Physical examination showed considerable enlargement of the liver. Conjunctival icterus was a relatively late symptom. When this arrived the patient was usually feeling well despite the presence of asthenia, which persisted for a time. The symptoms due to icterus in general, as presence of bile in the urine, pruritus, etc., were more or less in evidence. Only in the pregnant woman was the disease severe, and about the only deaths occurred in these subjects. Autopsy on one case revealed absolutely nothing to account for the special morbidity. The liver showed considerable fatty metamorphosis and the adrenals were the seat of pathological alterations. The gravidæ all died of paradoxical syncopal attacks. Bacteriological and hematological studies yielded no positive finds. The only clew to the nature of the malady was the occasional coincidence of paratyphus bacilli in the blood, suggesting the possibility of a modified strain of this germ endowed with icterogenic properties.

STUDY OF THE URINE IN CRIMINOLOGY.

In a practical note in the *Annales d'hygiène* (cited in the *Journal de médecine et de chirurgie pratiques* for November 10), Remlinger of the Pasteur Institute of Tangier reports some curious results of a study of the urine of criminals as a means of identification. It has long been known that sex is readily betrayed by the urinary sediment the excretion of the female being characterized by the presence in health of large pavement epithelium from the external genitals not present in the male. The author or reviewer neglects to mention that while this holds good for health, similar bodies are found in males with urethral disease. Still, as is justly claimed, the test usually answers in practice.

While no actual expertization is narrated Ramlinger deals with certain supposititious cases. Thus suppose a man or woman is found in bed in the morning assassinated. The medical coroner or equivalent should not fail to have the urine in the chamber pot examined from this viewpoint. If the subject be a man, the presence of certain epithelia known to urologists as almost peculiar to women would be near evidence that a female person of some kind had been with him during the night. Conversely if the subject found dead be a woman the presence of spermatozoids would betray the fact that a man had occupied the room with her. But a little reflection will show that a complete analysis could throw light not merely on the sex but the personality of the voider of the urine. Thus in the art of detecting the perpetrator of a crime the operator could readily perhaps secure urine passed by the suspect and the presence of albumin, casts, sugar, etc., might constitute a valuable lead. As the author suggests, identification by this means might become so developed that the underworld would be forced to adopt a new caution "never urinate."

The editor recalls at least one case in which an employee who feared that his boss would not live long resolved after consultation with a medical man to bribe a loose woman with whom the sick man consorted to obtain some of the latter's urine. The outcome of this resolution is unknown but doubtless

medical practice is full of analogous cases. We do not, of course, refer to the custom of obtaining a specimen of urine vicariously through a man's wife in order not to alarm a nervous husband, but to cases in which some element of chicane enters. The detective would be compelled to use subterfuge and bribery in order to obtain his samples, and it seems doubtful whether legal evidence based on such activities could be introduced to convict a man, however valuable it might be to the State.

Malaria as a Simulator of Disease.

It has usually been said that syphilis is the mocking bird among diseases, and this may still be true of chronic affections, but malaria is equally potent as a simulator of acute diseases, as is well shown by an article by Castellani, in the *Archives Médicales Belges* for August, devoted to tropical affections on the Balkan front. The following is a list of apparent diseases which were in reality masked malaria: Purpura, pernicious anemia, polyneuritis, typhoid fever, tetanus, rabies, sleeping sickness, dysentery, cholera, cirrhosis, Raynaud's disease, orchitis and orchiodynia, various dermatoses, appendicitis, peritonitis, cholecystitis, pancreatitis, and abscess of the liver. This list by no means exhausts the possibilities. Some of these simulations seem so incredible that a brief review is in order. In regard to tetanus the author has seen four cases in which patients presented trismus, opisthotonos, and tonic convulsions. The normal temperature would perhaps have put the medical man on his guard about the possibility of tetanus, but blood tests showing the plasmodium and the curative power of quinine told the whole story. In regard to rabies, the author while in Colombo was summoned to see a supposed case of the latter. There was at the first contact with the case a paroxysm such as occurs in rabies, with temperature of 102° F. The mere sight of water provoked a spasm of the larynx. The author first examined the spleen, and found it quite large. Having a portable microscopic outfit, he then examined a drop of blood and found the plasmodium. Fifteen grains of quinine thrown into a muscle caused all the phenomena of rabies to vanish in a few hours. The author admits that this case may have been hysterical hydrophobia, but the blood test could not be disregarded. Of conditions not listed above as masked malaria may be mentioned a syndrome which suggested both yellow fever and Weil's disease. In a case of this type death occurred despite heroic quinine treatment, but the blood count was evidently decisive. There was also a single case in which Malta fever was exactly simulated. But not all borderline cases were malarial, for alongside of the masked malarias the author found true Malta fever, kala azar of adults, recurrent fever, pappataci fever, and a host of other tropical and exotic affections.

Influenza Pneumonia in 1847.

Dr. Arias-Carvajal, who has been reading accounts by eyewitnesses of the epidemic of 1847 as it visited Southern France (*El Siglo Medico*, October 5) states that the description applies word for word to the recent visitation in Spain. The old episode began on November 5, in the city of Montpellier; and exactly one month later was at its acme. The affection was readily identified with a visitation ten years earlier. Dr. Rodrigues, then practising in the city, termed the malady "grippe" the word having been first used in France by Sauvages in an epidemic in 1743. This author referred to another visitation in 1831, of great contemporary interest because it began in August during an unusually hot and dry summer, which agrees in every way with the summer of 1918 in Europe. The identity of these epidemics with the present day one having thus far been upheld a description of the symptoms would be redundant, but we may justly cite the references to pneumonia which should serve to lay the ghost of rumors of exotic pestilences. The term pneumonia was evidently not in general use but "pulmonary fluxion" and "suffocative catarrh" replace it. A young married woman perished rapidly, literally suffocated by a pulmonary fluxion, which could not have been prevented. A man of 31 who rose at night for a drink of water was seized with a paroxysmal cough and orthopnea. He was at once bled to his advantage, but on the third day was dead. More suggestive was the fate of Professor Delmas of the Faculty who was attacked with bronchial catarrh which rapidly extended to the parenchyma of the lung and was promptly followed by death. Aside from such deaths the majority occurred in the aged and "asthmatic," as a result of a kind of "ingurgitation of the lungs," apparently not one of the victims of this class escaping. Children were attacked by a "suffocative catarrh." The Spanish writer naturally sees in all of these deaths only fatal secondary bronchopneumonia. Of interest is the state of the tongue which is described as "crapulous," referring perhaps to the appearance of the tongue after a debauch. In the present epidemic much stress is laid on a typical grip tongue, a heavy white coat with red, raw edges and tip. This tongue has been figured in some journals and is none other than the strawberry tongue so common in scarlet fever. The alleged sense of pain and constriction under the sternum, so common in the recent epidemic, is mentioned, as is also the mild angina regarded by some today as characteristic in appearance.

A Lay Medicopsychologist.

The novelist Huysmans has been added to the already long list of lay medicopsychologists, which includes Shakspere, Balzac, Poe, de Maupassant, Dostoyevsky, and others, whom the medical profession have been willing to acknowledge as such. From an editorial article in *Le Progrès Médical* for September 14, we select some of the statements of Dr. Levrat, who has written a brochure on the medical knowledge of Huysmans and of another writer, Lavalée, who has published an essay on the character of Huysmans himself; so that the author may be studied in his creations. It is enough to state that he was a misanthrope and a born "knocker." His character of Tibaille in the "Soeurs Vatards" was the first of a type of depraved personages sketched who were mentally disequilibrated, and in all of whom Lavalée sees Huysmans himself. Prich-

ard, in "A Rebours," is morally insane, and Follantin is a hypochondriac. All of the characters agree in having a bad heredity and in being eccentric, unstable, without family affection, misanthropic, bored with life, antisocial, and ever on the lookout for new sensations and experiences. Their degeneracy can readily be diagnosticated by the medical reader. Huysmans cannot write about goodness and good people, but he does show that these personages come to evil through their inborn dispositions. They finally arrive at the commission of the worst offences, or those thus regarded by normal men. Their bent sometimes leads them to pseudoreligions just as it causes them to commit blasphemies and sacrileges. Thus far, medicopsychology does not appear in any surprising degree, but a further study shows clearly the presence of fixed ideas and obsessions, various types of hallucination, impulsive acts, and exaggerated doubts and scruples. A study of *folie de doute* in one of his characters is so correct that it might have been taken from the pages of an alienist. One character becomes converted to religion, but apparently is hardly changed thereby in his personality. It is said that Huysmans, as might have been anticipated, was no lover of the medical profession. To sum up, the great skill with which he drew his characters was due to familiarity with all the vagaries of psychasthenia, and these he found within himself.

News of the Week.

Annual Report of Charities Aid Association.—This report emphasizes the overcrowded condition of the New York State hospitals for the insane and the need for immediate expansion of the system. The thirteen hospitals of the State have a capacity of 28,997 patients, but the end of the fiscal year found them housing 35,462, showing 22.3 per cent. overcrowding. The State is now committed to the construction of a new hospital at Creedmore and one at Marcy, a psychopathic hospital in New York City and a new State hospital for the Metropolitan District to take the place of the Mohansic institution. The association urges that the building program be pushed and that additional sums be appropriated as soon as possible.

Would Make All Women Nurses.—Louis I. Frank, Superintendent of Beth Israel Hospital, New York, has written letters to ex-Presidents Taft and Roosevelt and to the Surgeons General of the Army, Navy, and Public Health Service, and also to a number of prominent sociologists, urging that with the coming of peace Congress should enact a law for the universal training of females in nursing. Mr. Frank points out that the hospitals at the present time could accommodate 2,000,000 nurse students, and asks that at about the age of sixteen all girls shall be required to spend two years at theoretical and practical nursing. He says this need is pressing since there are not enough nurses to care for the illness incident to demobilization.

Woman Sues Hospital.—A suit for $50,000 has been brought against a hospital in this city by a woman who alleges in her complaint that her face has been disfigured as the result of exposure to rays of radium for twelve hours, while she was undergoing treatment for the removal of a mole.

Frank Richardson of Cambridge, N. Y., has been appointed commissioner of narcotic drug control by Governor Whitman. This commission was created by an act of the Legislature of 1918.

Miss Julia Lathrop, Chief of the Children's Bureau of the Department of Labor, and Miss Grace Abbott, Director of the Child Labor Division, have sailed for Europe, where they expect to consult with child welfare experts in England, France, and Italy.

Gifts and Bequests.—The will of James R. Steers provides for the following bequests: Presbyterian and Sloane Maternity Hospitals, $10,000 each; the Post-Graduate, Manhattan Eye and Ear, Woman's, and St. Andrew's Hospitals, $5,000 each.

Under the will of Jean B. Bourdis, French Government institutions for blind and hopelessly crippled soldiers receive a bequest of $96,500. The Asylum St. Vincent de Paul, the Ecole Maternelle of Paris, and the New York Hospital receive $3,820 each.

By the will of the late James Crawford, of Scranton, Pa., the sum of $100,000 is bequeathed to the Crawford Hospital and Boys' Home of India.

By the will of the late Homer H. Partridge of Philadelphia the sum of $1,000 is bequeathed to the Presbyterian Hospital.

The Association of Ex-Resident and Resident Physicians of the Philadelphia General Hospital held its thirty-second annual dinner at the Hotel Rittenhouse on the evening of December 3 under the presidency of Dr. Oscar H. Allis. Toasts were responded to as follows: "Blockley in the Sixties," Dr. Oscar H. Allis; "Blockley Clinics and Clinical Teachers," Dr. Richard C. Norris; "Blockley: A Vision," Dr. Wilmer Krusen; "Blockley Women-Physicians," Dr. Marion H. Rea; "Blockley Resident Physicians," Dr. R. W. Watson.

Dr. Edward Martin, who recently resigned from the John Rhea Barton Professorship of Surgery in the University of Pennsylvania to enter the Medical Corps of the United States Army, has been elected Emeritus Professor.

Influenza a World Plague.—A writer in the *Times* of London states it is reasonable to believe that throughout the world about 6,000,000 persons perished from influenza and pneumonia during the last three months. It is estimated that the war caused the death of 20,000,000 persons in four and a half years. Thus it may be seen that influenza has proved itself five times deadlier than the war. Never since the black death has such a plague swept over the earth. It is pointed out that this illustrates the need of a new survey of public health measures.

A report from the Pennsylvania State Department of Health announces that 45,000 orphans were created during the present influenza epidemic in that State.

Health Department to Sell Emulsified Milk.—In view of the fact that present milk prices have inflicted injury to the health of the people, and especially of the younger generation, the New York City Health Department has decided to sell emulsified milk at its milk stations. The emulsified milk is made of ordinary milk with the butter fat extracted and the water dried off. The powder which remains forms the basis of the emulsified milk,

which pediatricians recommend as equal to "Grade A" milk. The emulsified milk will be retailed by the Health Department for eleven cents a quart.

In Memory of Doctor Samuel Adams Green.— Appreciations of Dr. Samuel Adams Green were given at the meeting of the Massachusetts Historical Society, Boston, on December 12. Dr. J. C. Collins Warren spoke of his medical career, so closely associated with the private and public institutions of the city of Boston. Judge Robert Grant, who was Dr. Green's private secretary when he was mayor in 1882, paid a tribute to his memory in the service of the city, and Julius H. Tuttle, long associated with him in the library of the Historical Society, spoke of his services to the society during his membership of nearly 59 years.

Dr. Eugene A. Stanley of Waterbury has been appointed superintendent of the State hospital for the insane at Montpelier, Vt., to fill the vacancy caused by the death of Dr. W. L. Wasson.

Dr. Martin Stiles has been appointed Health Officer of Walla Walla, Wash., to fill the vacancy caused by the resignation of Dr. J. E. Vanderpool.

Dr. Esther Sunderlof has been appointed assistant physician in the *x*-ray department of the Boston City Hospital.

Dr. Anthony Bassler has been appointed professor of gastroenterology at the Fordham University Medical School, New York.

Dr. William V. P. Garretson has recently been appointed consulting neurologist to the Hospital of Functional Reeducation of Disabled Soldiers and Sailors, which is affiliated with Cornell Medical College, New York.

Dr. Colin Fulkrod of Philadelphia has been elected to the Board of Governors of the Maternity Hospital to fill the vacancy on the staff caused by the death of Dr. Clarence H. Gray.

Dr. William T. Shoemaker of Philadelphia has been appointed ophthalmologist to all the American Hospitals in England. Doctor Shoemaker went to France in 1917 as ophthalmologist to the Pennsylvania Hospital Unit.

Medical Society Elections. — The Morgan County (Ala.) Medical Society, at its annual meeting held in Decatur, Ala., December 7, 1918, elected the following officers for the ensuing year: *President*, Dr. W. C. Bailey, Decatur; *Vice-President*, Dr. A. M. White of Harzelle; *Secretary*, Dr. William Dinsmore, Albany.

The Shreveport (La.) Medical Society, at its annual meeting held December 3, elected the following officers for the ensuing year: *President*, Dr. J. A. Hendricks; *First Vice-President*, Dr. R. F. Harrell; *Second Vice-President*, Dr. A. D. Hatcher, Greenwood; *Secretary* (reelected), Dr. W. P. Butler; *Treasurer*, Dr. A. A. Herold.

The Pierce County Hygiene Society (Wash.), at its annual meeting held in Tacoma, December 5, elected the following officers for the ensuing year: *President*, Elmer Hayden; *Vice-Presidents*, Judge O. G. Ellis and U. E. Harmon; *Secretary*, F. Geigen; *Treasurer*, Walter J. Thompson.

Obituary Notes.—Dr. Samuel F. Brothers died suddenly at his home in Brooklyn, N. Y., on December 18, aged 55 years. He was a graduate of the New York College of Pharmacy in 1885, and of the College of Physicians and Surgeons, in 1890. He was the organizer of the Columbus Dispensary. He was formerly assistant in pediatrics to Bellevue Hospital and assistant in surgery at the Mount Sinai Dispensary. More recently he was gynecologist to the former Zion Hospital and Dispensary, the Metropolitan Hospital and Dispensary (now the Beth David), and the Beth Israel Dispensary.

Dr. Alvin M. Strusse, President of the Rockefeller Institute at Guatemala and Chief of the Supreme Council of Salubrity, died of pneumonia, at Guatemala, on December 18, aged 28 years. He was a graduate of Jefferson Medical College, in 1914.

Dr. Watson L. Wasson, superintendent of the State Asylum for the Insane at Randolph, Vt., died of acute dilatation of the heart, on November 24, aged 44 years. He was a graduate of the Medical Department of the University of Vermont, in 1901, and a contributor to the medical literature on insanity, alcoholism, and eugenics.

Dr. Eliza F. Pettingill died at Philadelphia on December 2 at the age of 77 years. She was graduated from the Women's Medical College of Pennsylvania in the class of 1864. She was one of the visiting physicians to the Women's Homeopathic Hospital and a member of the American Institute of Homeopathy.

Dr. Joseph Vincent Kelly died at Philadelphia on December 6 at the age of 74 years. He was graduated from Jefferson Medical College in the class of 1868. He served in both army and navy during the Civil War. He was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Correspondence.

AN EVENING CLINIC FOR THE DISABLED.

To the Editor of the Medical Record:

Sir:—The Red Cross Institute for Crippled and Disabled Men, 311 Fourth Avenue, has been maintaining an employment bureau for disabled men for about one year. This bureau has received the greatest cooperation possible from the medical profession in this city. When the bureau was first started it was decided that placements were to be as scientific as possible and for that reason, wherever it was possible to secure a diagnosis of the patient's case before referring him to employment, a letter was sent to the hospital. At first the doctors did not seem to understand the need of this diagnosis and very few of the letters were answered. It is interesting to know, however, that recently about 75 per cent. of these letters have been answered by the various hospitals and dispensaries in this city. The institute wishes to take this opportunity of thanking the doctors of this city who have cooperated in this way and sincerely hopes for a continance of their interest in the proper placement of disabled men.

In endeavoring to get work for disabled men one of the greatest needs appears to be that of an evening clinic. Many men come to the bureau for work who are perfectly capable of following some light employment if they continue their treatment at the hospital two or three times a week. Such men

usually come to us for work when their funds are very low. Their earning ability may not be as great as it was before their accident. It would therefore be a very great difficulty for such men to have to pay for private treatment evenings.

There are two things that may happen to the man out of work who needs medical treatment. First, he may discontinue his treatment in order to do day work. This situation often becomes dangerous for other members of the worker's family. Second, he may take a night job in order to have the treatment regularly. There are objections to this, because the man is generally unaccustomed to night work. His family disturb him at day, as they are not used to the new schedule of hours. The waiting is so long in the dispensaries, often a large part of the day is taken up, so that the man cannot get sufficient sleep.

The theory that every disabled men who possibly can should find employment is a new one. We all know the moral effect upon a man not working when he can and when he wants to. In providing an evening clinic the medical profession can offer a great contribution in this problem. We do not want to see men selling pencils on the streets. If men want a chance to earn an honest living everything that human effort can do to help them should be done. Here is where the doctors can help and I know they will.

GERTRUDE R. STEIN,
Employment Secretary.

NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE MEDICAL PARLIAMENTARY COMMITTEE—WHITE BREAD—THE ANTISCORBUTIC VALUE OF VEGETABLE JUICES—DEMOBILIZATION AND THE SPREAD OF VENEREAL DISEASE.

LONDON, November 4, 1918.

THE belief that, despite the enormous administrative difficulties connected with the conclusion of the war, the country would proceed before Christmas to a general election was widely held, and was shared by the medical profession, with the result that a feeling became acute among some of our leaders of thought that the parliamentary position of medical men required profound improvement. From this belief sprang the institution of the Medical Parliamentary Committee, which, however, came into being too late to make itself felt as a practical force in the imminent election. Most of the constituencies had chosen their candidates, while it became apparent that any further candidates for parliamentary honors would largely be selected by the Coalition with a mandate to obtain good peace terms for the Allied Countries and the United States rather than to carry out domestic reforms; and, of course, it is in domestic reforms that the medical voice is required in Parliament. In the forefront, however, of the program of the Coalition (as Mr. Lloyd George's non-party government is briefly termed) occur promises of vast improvement in our housing and extensive attention to the needs of the operative and laboring classes. It need hardly be said that in all measures having such objects in view, medical knowledge and medical experience are invaluable. The Medical Parliamentary Committee therefore determined to do what was possible with regard to the approaching election, even in the very few days at its disposal, and it has already shown itself to be an active body. The Committee has made inquiries through the country to obtain the names of medical men who are willing to stand for Parliament, is ascertaining their party views, and keeping a list which will be at the disposal of the various election organizations in future contests. It is necessary that the Committee should ascertain by what party label a candidate desires to be signalized, for only in this way is it possible to ascertain in which particular direction party machinery can be brought to his aid; but every medical man who is selected in this way by the Medical Parliamentary Committee will understand that the medical view comes first with the Committee. This is of course the only way to regard the situation. The medical man has the same right to his general political views as has any other citizen, and it is certain that he will only get into Parliament as a representative of those general views and not as a representative of medicine. But the medical profession has also the right to expect from every medical man that, finding himself in Parliament, he will remember that the health of the people is his real responsibility. The Medical Parliamentary Committee has now associated with Dr. Arthur Latham in the secretaryship Dr. Charles Buttar, who for the last four years has been the untiring Chairman of Executive in the Central Medical War Committee. Money is being raised in the first instance among the members of the Medical Parliamentary Committee themselves for propaganda purposes, and the Committee has invited medical men to come forward as speakers wherever any medical candidates for Parliament desire such assistance. There are standing at the present moment twenty-eight medical men, of whom four may be said to be representative of the profession scientifically, namely, Sir Watson Cheyne, Sir Wilmot Herringham, Sir William Whitla, Sir Robert Woods. Sir Auckland Geddes and Dr. Christopher Addison, members of the outgoing administration, are both ex-teachers of anatomy and preliminary sciences, but hardly count as medical men, though the medical profession likes to include these distinguished politicians on its roll.

Doctors in this country are viewing with some regret the rapid return of the population to the use of white bread, for they consider that there is strong evidence for believing that the use of wholemeal bread has been valuable to the health of many. Whole-meal bread, that is, bread in which all but some 15 per cent of the wheat grain has been utilized in the flour, was introduced as a necessary measure of war economy, and was received in the first instance by the public with no alacrity. The Ministry of Food proclaimed its nutritive virtues, doctors and chemists swelled the chorus of official approval, but the public nibbled whole-meal bread with a virtuous air, as who should say: "We are winning the war by stern endurance." And truth to say, most of the war bread of three years ago was nasty eating. The wheat-flour was mixed with varying, almost capricious, quantities of other cereal flours; each different mixture required some different baking to get a good result; all bakers had not the necessary plant to cope with the variations. Of course, experience

quickly won the day, and now for many months we have enjoyed admirable bread, though not the white loaf of pre-war days. Habit in many, and predilection in others, is now bringing about a return to white flour, and the needs of animal stock are likely to help in making that return complete. For, of course, the whiter the flour the more abundant the husks—or "offal," to use the technical term, and the fatter the pig. The "offal" is not wholly wasted by going to the pig, but its return to man as pork is attended by considerable metabolic reduction. So that on the grounds of economy whole-meal bread can be defended; on the grounds of health its claims are loud; on the ground of palatability every one must speak for himself. Palatability does not lend itself to exact scientific measure, but it has a scientific value, inasmuch as food that is relished is always better digested.

I alluded in a previous letter to the valuable work done by Dr. Harriette Chick and her collaborators at the Lister Institute in regard to the anti-scorbutic values of lemons, and, in almost equal degree, of oranges. The work has been continued along other lines, and in view of the position of the British milk supply may prove to be of the first importance. In studying the distribution among foodstuffs of the antiscorbutic accessory factor, a group of workers in the Lister Institute gave particular attention to milk. A preliminary report of these investigations was published in *The Lancet*, the results showing that cow's milk, even when fresh, is poor in anti-scorbutic properties; from which it results that much of the criticism passed on "infant foods" (proprietary) as incentives to rickets may have been unfairly directed. For it would seem that only a large daily ration of fresh milk could possibly contain a sufficiency of the anti-scorbutic factor, and this is unobtainable in Great Britain under the existing machinery for collecting, transporting, and distributing the milk. Dr. Chick, in association with Miss Mabel Rhodes, has now made an investigation of the antiscorbutic properties of oranges, grapes, turnips, carrots and beet-root with a view to their juices being adopted as adjuncts to the dietary of infants, and the following summary of their work is of genuine medical interest. They find:

1. Cow's milk possesses antiscurvy properties, but these are present in small degree in comparison with other antiscorbutic foodstuffs. Its value in this respect is further reduced after heating or drying. It is therefore advisable to provide some extra anti-scorbutic material in the diet of infants nourished upon heated or dried cow's milk.

2. The antiscorbutic value of various materials that might suitably be included in an infant's diet has been experimentally determined by means of experiments with guinea-pigs. Among fresh fruit juices that of the orange is easily the most suitable, and possesses a value about ten times as great as that of fresh grapes. Of the raw vegetable juices examined, raw turnip juice proved to be far the most potent, approximating in value to raw orange juice; the raw juice of carrots was found to be much inferior, and that of beet-roots failed to prevent scurvy in the largest dose (20 c.c. daily) that could be administered to the experimental animals.

It will be seen that the view is supported which was put out by Hess and Fish four years ago in the *American Journal of Diseases of Childhood* and last year by Miller in the *Cleveland Medical Journal* that incipient scurvy among artificially fed infants is not a negligible danger, and that the addition of new fruit juice to the diet of such children is a reasonable and even valuable precaution.

It has been the unfortunate experience of the past that the demobilization of armies has been attended by the spread of venereal disease among the civilian populations. It is perfectly natural that there should be present at such a time as demobilization great exaggeration of the circumstances which promote sexual intercourse. There is large resumption of martial relations, in condition almost of remarriage, many marriages between young people are consummated, and illegal unions, generally of a very temporary nature, are formed galore. The demobilized troops while on service have been placed with regard to venereal disease, at one and the same time, in extremely good and extremely bad conditions with regard to infection. During active service there was little opportunity of infection occurring, while if it did occur segregation and therapy were prompt and concealment of illness heavily punished. But on leave all these safeguards were withdrawn, and on leave accident as much as temperament dictates the incidence of venereal diseases among soldiers, officers or men. They have been cut off from the natural outlet of passion for a long period, and while a certain proportion are able to remain chaste, the effect of discipline holding good in the absence of its penal restrictions, a certain proportion are not so strong-minded. This latter class are exposed in bulk to common sources of infection during the whole of their leave time and accident determines whether the chances of infection are rampantly present or fortunately absent in the locality where the leave is spent. In a war of such duration as the one now concluded, a large proportion of officers and men have obtained leave, and the vast opportunities for license and its concomitant dangers have been taken advantage of, as is shown by a debate which took place in the House of Lords at the end of November to consider special measures of precaution upon demobilization. Lord Sydenham, chairman of the National Council for Combating Venereal Disease, on that occasion solemnly warned the Government that, if such measures were not taken quickly, there would be serious results to the whole population extending over many years, adding that the necessary legislation had not been taken in time, and that the only measure on the statute book, namely, an act dealing with quack remedies, was of no practical use. Lord Muir Mackenzie, who had presided over a committee which took evidence on all these points, complained that that committee was belated in appointment, so that no chance had been given for introducing a bill embodying any recommendations which it might make, but he urged that the next Parliament would take up the matter in the light of the information that was now available. The probability is that nothing practical will be done for some weeks, as Parliament is prorogued to make way for the General Election, and the new members will not assemble till January at the earliest. But

the feeling among medical men is that while political machinery is arrested and debating has ceased in Westminster, the permanent officials of the Government Departments are not rendered inactive thereby, but on the contrary obtain a freer hand. The Local Government Board will be expected to be aware of the dangers which must arise from the release of a large number of infected men and to be ready with arrangements for meeting the evil. Lord Sydenham's Council have published recommendations which should be carefully considered by the Board and all other Departments concerned. One of these goes to the root of the matter, for it suggests that no sailors or soldiers should be discharged while in an infective stage; they incurred the disease while in the service of the country, and it is the business of the country to return them to society in as fit a condition as possible. The sense of this recommendation is obvious. The Navy and the Army have got the men in their disciplinary control, can watch their treatment stage by stage, and can compel the measures necessary to make them safe members of society. It is estimated that this recommendation concerns at least 300,000 men, but a large proportion of these would in former days have been considered to be cured. For the general population many treatment centers have been established in England and Wales at which infected citizens, whether recently belonging or not to the Forces, can obtain treatment, with as much privacy as the organization can contrive, at the hands of specialists, while at these centers the general practitioners of the neighborhood are invited to attend, so that everywhere they may familiarize themselves with techniques of treatment which have evolved from comparatively modern medical science. Here is at once a direction in which the cure of the infected and the prevention of infection can both be greatly strengthened. These centers require immediate multiplication. Many Army doctors have now specialized in the treatment of venereal diseases, and their services should be used in connection with the establishment at all large provincial hospitals of centers for the treatment of venereal disease. And it is at these centers that the terrible problem of the woman infected with gonorrhea will in the end have to be treated. At first it will be difficult to sweep the women into the therapeutic net. Many women hand disease on with no idea that they have anything the matter with them; and even when their dangerous state is ascertained the cure of chronic gonorrhea in the female remains a terribly disappointing task. It is a task, however, that will have to be tackled in this country, and perhaps in the United States, if only because chronic gonorrhea in the female is the most potent cause of sterility.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

INCREASED EFFORT TO ARREST GRIPPE—PARIS HONORS HER WARRIOR DEAD—THE PARIS GAMIN AND OUR WAR TROPHIES—PSYCHOLOGY OF THE ARMISTICE CELEBRATION.

PARIS, November 25, 1918.

THE Rector of the Academy of Paris has ordered all the lycees and colleges to be closed all this week and until next Sunday, inclusive, in consequence of the epidemic of influenza. The Prefect of the Gironde has prohibited all theatrical and moving picture performances, concerts, and lectures in his department, and has ordered the schools to be closed and religious services to be limited as much as possible. All cafés, restaurants, and drink-shops are to be closed at 9 p. m. and all indoor public places are to be frequently disinfected. The mayors of Limoges and Tours have issued similar orders. All the schools and colleges at Bourges have been closed.

Paris, for the fifth time since the beginning of the war, observed the feast of All Saints by the customary pious pilgrimages to the cemeteries. The rainy weather of the preceding day had given way to bright sunshine that seemed symbolic of victory. The cemeteries were thronged with people, including many women in deep mourning, who had come to lay wreaths, in which chrysanthemums were predominant, on the graves of their relatives, some of them soldiers who had died in the military hospitals. The French President and Mme. Poincare, accompanied by municipal councillors, visited the cemeteries of Bagneux, Ivry, and Pantin, and deposited flowers on the soldiers' graves. Mr. Pams, Minister of the Interior, went to the Montparnasse cemetery. Over 130,000 people went to the Bagneux cemetery, Paris, during the day. The number at Pere Lachaise was over 62,000, at Montparnasse 40,800, at Pantin 85,400, and over 46,000 at Ivry. At Suresnes, near Paris, the cemetery was visited by the Municipal Council and many people, who laid wreaths on the graves of the American soldiers in token of France's grateful remembrance of the men who had sacrificed their lives on her soil. The graves near the front were not forgotten, and M. Abrami, the French Minister, conducted the ceremonies at the cemeteries of Bouresches, Belleau, and Chateau Thierry, where French, American, and British lie side by side.

If Poulbot discovered the Paris gamin who drills and wages mimic warfare in the dismal ruins of the demolished houses of Montmartre, it was Clemenceau who gave him the real guns and bigger manoeuvring grounds of the Place de la Concorde. For all the boys of the French capital, thanks to the launching of the new Victory Loan and the military display of captured enemy guns, are daily delighted with the splendid and unprecedented toys that Krupp's have made for them, and which the French Government have put at their disposal. What matter that, like the boxes of lead soldiers and mechanical trains of peace days, these marvellous and monstrous playthings were "Made in Germany"? Essen has this time builded well; the blasting furnaces and the grimy Hun workmen have wrought infinite desolation—now they are providing infinite joy. It is not for the childish mind to remember that the murderous machines, now filling the peaceful paradise of Young Paris, were bought with blood. The juvenile artillerymen, absorbed in the practical and serious business of soldiering, have no time to reflect upon their part in the composition of this unforgettable picture. They play with an earnestness, a zeal, such as they have never had before, oblivious to all but the guns and the imaginary enemy, whom they mow down in battalions. All ages, from four to fourteen, are

here among the howitzers—from 3-in. to 12-in. howitzers—the huge trench mortars, the minenwerfers, the machine-guns, the whole paraphernalia of death and destruction. The French boy knows as much about these German guns as the German gunners. He knows, because he has found out for himself. No intricate detail escapes him. He is avid of knowledge, and learns by his own nimble intelligence. He needs no masters, no manuals. Sometimes, perhaps, but very rarely, does some complicated piece of mechanism puzzle him, and he will turn for an expert opinion to the passing artilleryman. The passing artilleryman, no matter how tremendous and grizzly his moustache, spares no pains to enlighten his excellent young colleague, and the two heads bend together over the cranks and tackle.

Paris for two days after the signing of the armistice was one wild city of abandoned rejoicing: forty-eight hours, with no remission, night or day, and for the first time in four years the city has been illuminated. No more air raids; no more searchlights sweeping the sky, or sentinel airplanes hanging overhead in watchful waiting for the first distant appearance of an enemy. The Champs Elysées looked like day all of two nights, and some of the buildings were outlined, as in bygone days, by gas jets or incandescent lamps. All business was suspended, and shop girls and clerks, soldiers and civilians were constantly parading up and down the boulevards and avenues, arm in arm, the full width of the street, with banners, flags, bunting, flowers, bands, trumpets, horns, bells, and even tin pans, for lack of other instruments. It seemed they could not make sufficient noise to relieve the pent-up feelings of four years of anxiety, grief, and privation.

One old woman standing beside me said, while the tears coursed down her furrowed cheeks, "My boy is dead, but I hope he can see and hear this rejoicing; it will make him better satisfied." Lorries, camions, autos, all sorts of vehicles were pressed into service, decked with flags, bunting, posters, portraits of the great leaders—every country was represented. Traffic was wholly suspended. All thought of affairs and the ordinary routine of life was swallowed up in the one universal rejoicing. The most astonishing thing of all was the crowd. Where did they come from? It is known that Paris has lost one-third of its population by death, wounds, missing, removals to smaller cities where the cost of living is less; but no one would have suspected it from the ceaseless streams that have filled the streets for two days.

The ceremonies at the statue of Strasbourg, which for forty-seven years has never been free from emblems of mourning, will remain vivid in memory for all time. The Alsace-Lorraine Society came in a great body and before the massed thousands and in the presence of the members of the Government removed every trace of mourning, decked the statue in flowers, the national flag and arms, and the veterans of 1870 fired a salute while the crowds fell on each others' necks, sobbing for very joy; hundreds and hundreds filed by kissing the flag or even the bare stone if they were not able to reach the front of the noble monument itself.

OUR CANADIAN LETTER.

(From an Occasional Correspondent.)

CARE OF THE FEEBLE-MINDED IN CANADA—INFLUENZA—SOLDIERS' CIVIL RE-ESTABLISHMENT HOSPITAL—ORGANIZATION OF VITAL STATISTICS IN CANADA—OSTEOPATHS DEMAND LEGAL RECOGNITION IN THE PROVINCE OF QUEBEC—SCIENTIFIC AND INDUSTRIAL RESEARCH IN THE DOMINION—THE FOOD QUESTION—INAUGURATION OF A NEW SECTION AT THE ACADEMY OF MEDICINE OF TORONTO—ANNUAL MEETING OF THE NORTHWESTERN MANITOBA MEDICAL ASSOCIATION—OBITUARY NOTICES.

MONTREAL, December 17, 1918.

A CANADIAN National Committee of Mental Hygiene has been in existence now for some little time and has already justified its creation. There is a very considerable number of feeble-minded insane and epileptics in the Dominion, and it goes without saying that to allow such irresponsible persons to be at large is to permit a constant menace to the general population. Moreover, at the present time it is peculiarly fitting that adequate steps should be taken, not only to safeguard the public from the source of danger but to care for the men coming back from the front nervous and mental wrecks. The Committee, indeed, has an immense amount of work of an arduous and important nature to do in the near future. Fortunately, the fact is fully recognized by the Committee, and a policy is being formulated whereby the problem of the feeble-minded insane and the mentally deranged or defective will be dealt with in all parts of Canada. In accordance with this wise policy it has been decided to have a branch of the Canadian National Committee of Mental Hygiene in Montreal. With this end in view, a meeting was held recently in the house of Col. Colin K. Russell, when the matter was discussed. There were present at the meeting most of the Montreal members of the Committee under the presidency of Sir Vincent Meredith. Among other decisions arrived at, was to make a comprehensive survey of the feeble-minded and insane in the city of Montreal, and to endeavor to apportion as accurately as possible the relation of these disorders to crime, prostitution, and pauperism. Dr. J. C. M. Hincks, secretary of the Committee, pointed out that the chief reason why Canada was backward in providing for the treatment and care of the insane and mentally defective was because no coherent policy was followed throughout the Dominion, that is, the provinces had never been furnished with a constructive policy to cope adequately with the situation. This explained the action of the National Committee in placing its services at the disposal of provincial governments rather than in concentrating their efforts of reform upon the federal authorities. Referring to the men from the front who had come and were coming back broken mentally, the speaker outlined the need of efficient treatment of nervous and mental cases in suitable hospitals, and also drew attention to the demand for a follow-up system for discharged patients if the best results were to be anticipated. The Invalid Soldiers' Commission and the Committee had come to an agreement to appoint an inspecting psychiatrist to visit hospitals. Lieut.-Col. C. K. Russell then gave a sum-

mary of the work of the National Committee in connection with the army. With regard to immigration, he said that some interesting facts had been discovered by the Manitoba Public Welfare Commission. Statistics collected showed that the number of foreign born in jails and asylums for the insane and feeble-minded greatly exceeded those of Canadian birth. Col. Russell said that the federal authorities would be informed of these facts in an attempt to bring about a more careful selection of future immigrants to Canada.

Influenza has not left Canada altogether. The schools of Whitby, Ont., have been closed again during the past two weeks on account of a recrudescence of the influenza epidemic, and it has been decided to keep them closed until after the Christmas holidays. St. Catherines' Board of Health has issued a modified closing order on account of the recent increase in the number of influenza cases. Dance halls, the public library and all schools have been closed.

A hospital building to cost half a million dollars is to be erected near Woodbridge, in the vicinity of Toronto, for the Department of Soldiers' Civil Reestablishment, the cost to be borne jointly by the Provincial and Federal Governments. The location is considered ideal for an institution to treat lung troubles, and it is said that all tuberculous cases may be collected there.

In order that it may be known with accuracy how many persons are born, married, and die, and concerning the diseases which prove fatal or are most disabling in a country, it is necessary that the vital statistics be organized. In the establishment of a public health system on a sound basis, an essential step is the formation of a bureau of vital statistics. A conference with this object in view was held in Ottawa in June last, when preliminary action was taken tending toward a scheme of Dominion and Provincial cooperation. The report of this conference has been issued recently. The chief difficulty in the way of formulating a system of vital statistics for Canada lies in the fact that the provinces have different legislation and different methods of collecting and coupling results, so that it is impossible to make comparisons or to mold the returns into comprehensive wholes, although it is obvious that health problems must be studied on a broad basis. The aim of the conference was to arrive at a scheme of uniform legislation and administration by the provinces and the setting up by the Dominion of a central health clearing house. Agreement was reached on the general principles involved and a bill and a set of forms were sketched for reference to a committee for final adjustment.

The osteopaths of the Province of Quebec have declared their intention to endeavor to secure the enactment of a bill of incorporation at the coming session of the Legislature. It may be said that legislation favoring osteopaths has been passed in Alberta, Saskatchewan and British Columbia. Opposition in Quebec to the efforts of the osteopaths to be placed upon the same level as those who have undergone the training called for by the State and have passed the examinations which qualify a man to practise as physician and surgeon, will be strenuous on the part of the medical profession.

At a meeting of the Reconstruction and Development Committee of the Dominion Cabinet on December 2, Dr. A. B. McCallum, administrative chairman of the Council for Scientific and Industrial Research, brought forward the long-considered proposal of the council for the establishment of a central institute for research. The idea is to cause to be erected immediately at or near the capitol a central laboratory building to cost approximately $500,000. The building at first will have accommodation for some fifty laboratories covering all the necessary industrial research subjects. In a general way it will be designed to fulfill for Canada the functions now performed for the United States by the Bureau of Standards at Washington and the Mellon Institute at Pittsburgh. In part it will provide modern scientific equipment and methods for investigating Canadian raw material, industrial processes and manufactured products. It is intended to serve as a national laboratory for standards of all sorts, for the testing of materials, for the discovery of methods for utilizing by-products of manufacture hitherto wasted, and generally for experimental work in the application of the sciences to industry.

Although the war has ended, conservation of food is almost as necessary as when fighting was in progress. The food situation in Canada is far from satisfactory, for while there is a slight decrease in the cost of living the prices of the most nutritious foods are still so high as to bear very hardly on those with limited incomes. It must be borne in mind that there are many such, and that the exorbitant cost of most articles of food is a distinct and direct menace to the public health. The members of a joint special committee of the State Legislature of Massachusetts have been in Montreal recently investigating as to the cost of fish. They found that fish prices here were nearly thirty per cent. lower than in Boston.

A Section on Obstetrics and Gynecology has been inaugurated at the Academy of Medicine of Toronto. The first meeting of this Section was held recently under the presidency of Dr. B. P. Watson, professor of obstetrics and gynecology at the University of Toronto. In the very interesting address given by Professor Watson, mention was made of the success obtained by the use of radium in cancer and fibroid cases, and in various pathological conditions of the ovaries and ductless glands.

The annual meeting of the Northwestern Manitoba Medical Association took place a short time ago. The meeting was well attended, the President, Dr. O'Brien, being in the chair. The officers elected for the current year were: *Honorary President*, Dr. O'Brien, Rossburn; *President*, Dr. F. A. Smith, Birtle; *Vice-President*, Dr. Hudson, Hamiota; *Secretary-Treasurer*, Dr. Tisdale, Kenton; *Committee*, Dr. Andrews, Minnedosa, Dr. Swallow, Russell, and Dr. Fryer, Virden.

Capt. I. R. Guifoyle, London, Ont., died at Witley Camp, England, on October 28.

Dr. James Ewart Brown, F.R.C.P., of Toronto, died on October 12 from the result of too close attendance to duty. He contracted influenza but continued his practice and died absolutely in harness.

The son of Dr. W. F. Hamilton of Montreal was killed in action shortly before the close of hostilities.

7. Cellulitis of the Upper Lid Due to a Foreign Body. A Report of a Case.—Alexander Rovinsky reports the following case: A boy of eight years of age was brought to the eye clinic of the Post Graduate Hospital, New York, with a history of having had a piece of wood "shoved" into his eye by a playmate some eight weeks previously. The right eye was enormously swollen and entirely closed by mechanical ptosis. No pain or tenderness was evinced on manipulation, and on forcibly separating the lids the cornea appeared transparent and the pupillary reaction normal. There was considerable chemosis at the nasal portion of the conjunctiva, and slight protosis outward; inward movement of the eye was somewhat limited. The patient was given some Burrow's solution for external application. When he returned two weeks later, swelling had abated to some extent and palpation revealed a firm, elongated body immediately under the lid. This proved to be a sliver of wood an inch long and a quarter of an inch wide, which was easily pulled out by the forceps. There was no reaction, ptosis gradually disappeared, and in three weeks the lid was normal in shape and motility. The author points out that, owing to the elasticity of the skin covering the lids and their loose attachment to subjacent parts, edema and ecchymosis resulting from trauma is much greater in the eye than in any other part of the body; it is necessary, therefore, to make a thorough examination to determine whether there is an open wound in the lid or any involvement of the orbit and eyeball.

7. Neurasthenic and Hysterical Cases in General Military Hospitals.—Major R. H. Trotter points out the great importance of appropriate treatment of hysterical and neurasthenic patients while they are in a general hospital awaiting transfer to a special hospital. The greatest vigilance should be exercised also in looking out for symptoms of neurasthenia in patients admitted for physical disease. There is a tendency to consider such patients as cases for treatment only at the neurological center, and when diagnosis is made to mark them for transfer to the special hospital and to take little further interest in them. Major Trotter believes that early treatment in war psychoneuroses is almost as important as prompt surgical treatment in appendicitis, and it should be remembered that a neuropathic habit quickly becomes fixed if left untreated. Although the facilities found in neurological centers may be essential for complete cure, emergency treatment could be given in the general hospital and, when a vacancy in the special hospital occurs, a patient well on the way to recovery might be transferred. Accurate diagnosis, confident prognosis, understanding sympathy and inexhaustible patience are the essentials required. The patient should, if possible, be subjected to partial isolation in a special case ward, without irksome restriction; the nature of his ailment should be explained to him, and he should be confidently assured of an early and complete recovery. In motor psychosis relaxation is secured by passive movements. Cases of flaccid "palsy" should be treated by manipulation, the patient's confidence being restored by the sudden interruption of manipulation as soon as muscular resistance becomes powerful enough to retain the limb in a momentary rigidity. Exercise and employment should be given at once, as the patient left with an idle brain will relapse or develop a physical neurosis. In the latter case, a psychoanalytical talk will often remove many doubts and difficulties in the patient's mind. The author remarks that it is an interesting speculation how far the reflex contractures of Babinski and Froment would be prevented by early treatment. He adds that visceral neuroses are often aggravated by essays in surgery.

5. The Curse of Immobilization.—J. W. Dowden from four years' experience of war surgery concludes that the lessons learned during these years have been, first, that nature is the most wonderful surgeon, especially when encouraged; second, that septic wounds should be thoroughly drained; third, that from the very beginning frequent passive and active movements should be carried out in cases of injured limbs, steadily increasing the range; and that splints should never be used except when absolutely necessary and then only for as short a time as possible, and should never interfere with passive and active movements. Massage he considers an excellent adjunct to active movements; electricity or baths he lays little stress on. In war surgery the future usefulness of the wounded must be borne in mind, the order of importance being muscles, joints, bones; not bones, joints, muscles. The danger signal in passive and active movements is pain. If, however, adhesions have formed after prolonged immobilization, pain must be endured while the adhesions are stretched or broken. Dowden believes that thousands of soldiers have been more or less disabled for life simply through prolonged immobilization of injured limbs, and cites as examples several cases that have passed through his hands. He says: "This needless disablement of men is really the most disheartening thing I know in the war," and closes with an expression of belief that "the future will see a great reaction from this most remarkable age of splints."

The Results of Preventive Vaccination of Infants Against Tuberculosis.—W. Kruse states that Friedmann's remedy (bacillus of tuberculosis from cold-blooded animals) is studied in this paper from the viewpoint of its prophylactic value. Friedmann first resorted to preventive vaccinations in 1912 to the number of 319. The cuti-reaction, negative in every case, sometimes became positive during treatment. The injection, made in the gluteal muscle at the dose of 1 cc., never produced unfavorable results. A certain number of children could be followed up to 1918 and serve to establish the results of vaccination.

The writer finds them encouraging, but this impression does not bear much evidence from the statistical tables offered by the writer, which have been made from an evidently preconceived opinion. To give but one illustration in point: The usual general mortality during the first years of life is, according to Kruse:

First year, 213 0/00; mortality from tuberculosis, 3.9 0/00.

Second year, 44 0/00; mortality from tuberculosis, 5.1 0/00.

Third, fourth and fifth years, 15.3 0/00; mortality from tuberculosis, 3.1 0/00.

The mortality of children observed by Friedmann and Kruse was:

First year, 38/216; and from tuberculosis, 0/216.

Second year, 2/173; and from tuberculosis, 0/173.

Third, fourth and fifth years, 4/422; and from tuberculosis, 1/422.

The writers have not hesitated to transform these fractions into percentage. Thus, the relative mortality of tuberculosis, usually of 3.9/213 during the first year, descends to 0/176 under the influence of vaccination; that of 5.1/44 falls to 0/11.6, but the relative mortality of 3.1/15.3 of the third, fourth and fifth years jumps to 2/9.1 on account of a tuberculosis presented by ONE (!) of the vaccinated children.

These statistics recall to mind a certain German hospital, where, in the lapse of one year, the mortality from para B typhoid fell from 100 per cent. to 0 per cent., the number of cases treated being one the first year with one death and one case with recovery during the second year. Several other details in the statistics offered by Kruse could be thus criticised, and it would be an easy matter, did space permit, to show up absolutely contradictory results from those desired to be brought out by the writer. In these circumstances Kruse's paper does not show the necessity of resorting to antituberculous vaccination of entire populations as the writer proposes.

On Lymphogranulomatoses.—E. Fraenkel and H. Much have not observed any return of this morbid process during the last few years. It is to be regarded as depending in a certain measure on granular rods described by these writers, a rod similar to, but not identical with Koch's bacillus.

Münchener medizinische Wochenschrift.

October 8, 1918.

The Nature of the Diuretic Action of Theocin.—Veil and Spiro attack the current conception of a diuretic action of theocin by direct action on the kidney. Certain peculiarities of the action of bodies belonging to the purine series should cast doubt upon a purely renal action, and the writers offer, to uphold another theory, the following experimental facts: In a normal subject (man or rabbit) the injection of theocin produces a diuresis with a transitory decrease of the chloremia and an increase in the albumin content of the blood (from concentration of the latter). The body weight decreases, partly from the diuresis, partly also from the increase of "extra-renal perspiration." The relative increase of the latter manner of elimination is even more considerable than the increase in the quantity of urine. On the other hand, the writers have made comparative charts of the urine from normal rabbits and rabbits upon which nephrectomy was done. The drop in the blood chlorides and the increase of albumin is observed as in the normal animal, although in narrower limits. The writers conclude that the action of theocin is to eliminate the water from the vascular system and send it into the renal glomerulae and cutaneous glands. The diuresis is merely a local manifestation of this phenomenon, which takes place in different degrees in all the tissues and the entire cutaneous surface. The explanation shows the reason for the progressive exhaustion of the diuretic action of the purine bodies as well as the fact that this action is of longer duration in oedematous subjects.

Central Pneumonia.—W. Hesse publishes some radiographic plates in support of the supposition that central pneumonia is a more frequent phenomenon than is usually supposed. It may remain as such during the entire evolution of the disease, thus offering insufficient clinical evidence for stethoscopic diagnosis, or, on the other hand, it may undergo the evolution of a classic lobar pneumonia. The writer even considers that the central genesis of pneumonia is the usual one. Hepatization then progresses from the region of the hilum toward the periphery of the organ. The progression of the pneumonic process, as well as its starting point, probably follow the bronchial tubes rather than the vascular or lymphatic systems.

War Food and Gastric Chemism.—L. Roemheld considers under the term of "war food" in Germany the absence of fats, the reduction of meat, the preponderance of carbohydrates and the richness of the diet in vegetable scoria and cellulose. He also includes the diminution in the consumption of alcohol and a marked increase in the use of tobacco. Besides these general food restrictions, a difference should be made between civilians and soldiers in the hospitals, where the diet is far less restricted than among the population. These differences, as well as the fact that it is necessary to carry out several test meals in the same patient, explain the divergence in the results reported by various observers. Roemheld found that the cases of anhydrochloria have been on the decrease since 1916, while those of hyperhydrochloria are slightly on the increase. This increase of cases of hypersecretion would undoubtedly be more evident if an epidemic of dysentery had not occurred and upset the statistics. The latter affection had a distinctly anhydrochloric action. Altogether, the effect of war diet has not been very considerable among soldiers, but the civilian population has suffered much more from it. From the standpoint of military aptitude, gastric chemism is not of much importance, no matter what may be its variations, if they are not accompanied by precise subjective disturbances.

Eosinophile Cells in Urinary Sediment; a Contribution to the Study of Membranous Ureteritis.—A. Edelmann and H. Lazansky report a few cases of nephritis with eosinophiles in the urinary sediment. The same phenomenon may be encountered in essential asthma. In nephritides the eosinophiles in the urine would seem to indicate a favorable prognosis, as they are absent in the nephritides having a lethal evolution, as well as in chronic nephritis. The writers also describe a case of right-sided ureteritis occurring in paroxysms of a nephritic type, in which the eosinophiles reached 92 per cent. The relationship with a muco-membranous enterocolitis might attribute an etiologic part to the "trichomona vaginalis" which was present in the urine in large numbers both at the beginning and the end of micturition.

Wiener medizinische Wochenschrift.

September 21, 1918.

Hemeralopia Considered as a Phenomenon of Deficiency Resulting from Nutritive Disturbances Contracted at the Front.—M. Gelencser again affirms the relationship of the symptom nyctalopia, which he erroneously calls hemeralopia, with nutritive disturbances denominated airtaminoses (Barlow's disease, scurvy, beri-beri, pellagra, etc.). He has frequently encountered the signs of scurvy in men sent to the rear for disturbances of nocturnal vision. Nyctalopia is, therefore, to be attributed to a want of important nutritive substances (vitamins of Funk) or to a disproportion

between the output of energy and alimentation. Night blindness may be a preliminary phase of scurvy, just as it can be an early symptom of the process. Its treatment is that of scurvy, calcium preparations being of great value.

The Treatment of Pulmonary Wounds.—E. von Klebelsberg offers a colorless contribution without anything original to this important question of war surgery. In cases of pleural hemorrhagic effusion of considerable amount he advises puncture of the pleural cavity, evacuation of the collection and the introduction of atmospheric air. Danger from infection by the air is *nil*. The writer insists upon the frequency of secondary tuberculous complications, which require careful isolation in all military hospitals.

Annales de Dermatologie et de Syphiligraphie.

September, 1918.

Wassermann Reaction in Tuberculides.—Schaumann of Stockholm relates cases which tend to throw doubt on the specificity of the Wassermann unless we concede that tuberculides so-called are often wrongly named. Ravaut, however, preceded him in this field, and moreover showed that salvarsan could sometimes cure these alleged tuberculides. Several other authorities have also noted this overlapping of syphilis and tuberculosis. The first case reported by Schaumann was one of typical erythematous lupus with so-called papulonecrotic tuberculides associated. She appeared to be free from any heredity of either disease, and as for acquired manifestations, there was only some enlarged lymphnodes in childhood. At the age of 29 the erythematous placques appeared and have persisted 15 years to date, with the evolution of new manifestations at the time of first consultation. Biopsy gave same diagnosis, animal experiment negative. Wassermann strong positive. Upon careful investigation there was absolutely nothing to suggest either inherited or acquired syphilis. She was seen three years later, when the skin lesions were still in evolution and still of the ultra tuberculide type. Wassermann still strongly positive. A mercurial course seemed only to aggravate the lesions, some of which recovered readily under carbonic acid snow. Some months later the evolution of tuberculides was still progressing in the form of papulonecrotic tubercles. The Wassermann was still positive, but the luetin test proved negative. The Mantoux intradermic tuberculine reaction was positive. The author was therefore forced to conclude that the lesions were tuberculous, although giving a positive Wassermann. A second case very briefly reported appears to be a duplicate of the first. There is no escaping the conclusion that the condition which underlies these nonsyphilitic manifestations is one which must be included, like leprosy, among Wassermann positive diseases. The reaction was as strongly pronounced as in florid syphilis.

Prurigo, Lymphadenia, and Eosinophilia.—Favre reports a case of this peculiar disease association which has been noted on numerous occasions. The mysterious disease prurigo is attended with enlarged lymphnodes and pruritus precedes certain diseases of the granulomatous type. The author has seen a group of these cases, and while the lymphnodes are primarily affected, foci of the same type were present at times in some of the viscera and skin, these being termed metastases. In regard to the preliminary itching the author admits that the condition is pruritus and that prurigo is a misnomer. This would imply that the early cutaneous lesions are artifacts. The cause of the pruritus would seem to be of vital significance—is this idiopathic or symptomatic of miscellaneous conditions? The author leaves this in part undecided, but states that it may vary in type if not in cause. One might confound it perhaps with simple itching followed by local infections and secondary slight adenopathies, but study of individual cases shows that no such simple sequence is present. The pruritus, in some cases at least, is essential, and appears in exacerbations during which there may be a febrile reaction. Again serious intercurrent lymphogenic phenomena may appear, as double pleuritic effusion, massive edema of the mammae, etc. There is also marked asthenia, and some of these patients die within a relatively short time after the first onset of pruritus. In a case of long duration the skin appears exactly as in chronic lousiness, the innumerable scratch marks being deeply pigmented. While the skin lesions may assume various types, there is no likelihood of confounding the condition with mycosis fungoides. Severest essential pruritus with a fever suggesting the undulant type, blood changes—notably eosinophilia—characteristic changes in the histological structure of the enlarged lymphnodes, all go to place this malady in the lymphadenia group. Of the half dozen or more of these which simulate and shade into one another, the so-called lymphogranulomatosis or malignant granuloma of some authors comes nearest to the malady in question. This in turn is comprehended by some under the general term of Hodgkin's disease. Tuberculosis was completely excluded.

Finska Läkaresällskapets Handlingar.

May-June, 1918.

Familial Occurrence of Pernicious Anemia.—Schauman's article appears in full in German. The author first refers to the modern tendency to see in this affection not a primary but a secondary anemia. This view is in part opposed by the occasional occurrence of familial cases, the first of which go back to 1891. Subsequent episodes have been reported by Sinkler, Bramwell, Caccini, the author (1900), and at least eight other reporters, including among Americans Cabot, Bartlett, Willson and Patek. In Bartlett's episode eight kinsfolk were attacked. But it is hardly necessary to quote individual reports, for it is now recognized that a not insignificant percentage of cases will if followed up be found familial. This is well shown by the author's experience, for since his attention was first called to the subject in 1900 he has unearthed 15 families with 2 or more members affected with bothriocephalus pernicious anemia and 7 other families with cryptogenetic pernicious anemia. Most interesting is the fact that both types of anemia can occur in one family. The genealogical researches are still in progress, and the author will probably be able to show that in at least a part of the nonfamilial cases members suffer, not indeed from pernicious anemia, but from anemic states of some sort. Furthermore, true pernicious anemia can be masked as heart or kidney disease, carcinoma, etc. On the other hand, bothriocephalus anemia, while it may not be severe, might simulate a familial affection because the members may be infected by the parasite at the same time. In some episodes of bothriocephalus anemia the kinsfolk had lived asunder in such a manner that a common infection was out of the question. Making all due allowances, however, the presence of a common endogenous factor seems undeniable, as in one family where several cases of pernicious bothriocephalus anemia and several of chlorosis occurred side by side. The latter is almost universally recognized as an endogenous malady. Another fact not previously stated is the serial occurrence of bothriocephalic and cryptogenetic in the same individual, who had been cured of a protracted parasitic case only to develop later a purely endogenous form.

Camp Universities in France.—In France medical colleges have been organized in the military zone, to be attended by military men and to teach military medicine. One of these will be near Rheims, where there are already 3000 beds and 70 students. The curriculum comprises surgery, medicine, histology and medical physics.—*Pathologia*.

Scabies in Holland.—According to Marsman scabies is not habitually prevalent in the Netherlands but of late has become so. The reasons are not far to seek for the country has been overrun with refugees from all quarters. Moreover, the proverbial cleanliness of Holland has suffered an eclipse through the scarcity of soap and new linen. Some concerted effort will be made to remedy this state of affairs and will begin no doubt with an ordinance requiring physicians to report all cases as fast as encountered. Already one municipality has appropriated money for combating the menace and much depends on the extent to which this precedent is followed.—*Nederlandsch Tijdschrift voor Geneeskunde*.

Society Reports.

AMERICAN ASSOCIATION FOR THE STUDY AND PREVENTION OF INFANT MORTALITY.

Ninth Annual Meeting, Held in Chicago, December 5, 6 and 7, 1918.

THE PRESIDENT, MRS. WILLIAM LOWELL PUTNAM OF BOSTON IN THE CHAIR.

Public Health Service Program for the Nation-Wide Control of Venereal Diseases.—Lieut.-Col. C. C. PIERCE U. S. Public Health Service, said that a great deal of thought had been given to the medical attack on venereal diseases in the United States, for it was a problem which not only affected the soldier and sailor but the civilian of to-day and to-morrow. Section 6 of the Act provided for the allotment to State Boards of Health of $1,000,000 each year for the two fiscal years beginning July 1, 1918, for the fight against venereal diseases. For the second of these two years the payment of the State's allotment was conditioned upon the expenditure of a like amount by the state in the prevention of venereal diseases. For the first of these two years this condition was not imposed.

1. State boards or departments of health receiving their respective allotments had to agree to the following cooperative measures: (*a*) Venereal disease must be reported to the local health authorities in accordance with state regulations approved by the U. S. Public Health Service. (*b*) Penalty to be imposed upon physicians or others required to report venereal infections for failure to do so. (*c*) Cases to be investigated, so far as practicable, to discover and control sources of infection. (*d*) The spread of venereal diseases should be declared unlawful. (*e*) Provisions to be made for control of infected persons that did not cooperate in protecting others from infection. (*f*) The travel of venereally infected persons within the State to be controlled by State boards of health by definite regulations that would conform in general to the interstate regulations to be established. (*g*) Patients to be given a printed circular of instructions informing them of the necessity of measures to prevent the spread of infection and of the importance of continuing treatment.

2. The Division of Venereal Diseases detailed to each of the various State boards of health an officer of the Public Health Service in uniform. His work was directed jointly by the Public Health Service and State Board of Health. The general plan of work for the State Bureau was as follows: (*a*) Secure reports of venereal infectives from physicians. (*b*) Suppressive measures, including the isolation and treatment in detention hospitals and establishment of free clinics. (*c*) Extension of facilities for early diagnosis and treatment through laboratory facilities for exact diagnosis and scientific determination of conditions before released as non-infectious. (*d*) Educational measures which included informing the general public as well as infected individuals, in regard to the nature and manner of spread of venereal diseases and measures to combat them. (*e*) Cooperation with local civil authorities in their efforts to suppress public and clandestine prostitution. (*f*) Accurate detailed records must be kept of all the activities of the venereal disease work, copies to be forwarded to the U. S. Public Health Service.

3. Local or legislative funds that might be available should be used by the State or city health authorities having jurisdiction for extension of the work.

4. In extension of the educational measures the State's health authorities and its bureau of venereal diseases should exert their efforts and influence for the organization of a state venereal disease committee for furthering the comprehensive plan for nation-wide venereal disease control.

5. The State health authorities should take such measures as might be practicable for the purpose of securing such additional legislation as might be required for the development of control of the spread of venereal infections.

6. The State allotment should be expended along general standard lines for all states and in accordance with an accounting system, to be forwarded by the interdepartmental social hygiene board, approximately as follows: (*a*) For treatment of infected persons in hospitals, clinics and other institutions, including arsphenamine and other drugs, 50 per cent. of the allotment. (*b*) In carrying out educational measures, 20 per cent. (*c*) In carrying out repressive measures, 20 per cent. (*d*) In general administration and other activities of venereal disease control work, 10 per cent. This distribution was provisional and subject to modification after conference and agreement between each State and the U. S. Public Health Service to best meet the needs of the particular State.

During the 609 clinic days represented there was a total of 25,224 visits to the clinics, with an average daily attendance of 41.09 at each clinic. There were admitted during the past month 2301 new cases. On November 15 there were 11,149 cases remaining under treatment. Twenty-eight thousand nine hundred and eighty-one treatments were administered during the month. Two thousand seven hundred and seventy-seven doses of arsphenamine were administered to syphilitics. A total of 2,933 prostitutes were treated in the clinics, detention homes and jails. Of the 833 prostitutes placed in detention during the month, 812, or 98.5, were found to be infected with venereal diseases. The remaining 21 or 2.5 were held for further diagnosis. Five thousand three hundred and sixty-five microscopical examinations were made. Nineteen of these were dark field illuminations for *Treponema pallidum;* 3267 were for release.

Conservation of Life of the Unborn and Newly Born Child.—Dr. RUDOLPH W. HOLMES of Chicago stated that the conservation of human life—of mother and baby—might be most happily realized by various correlated circumstances.

1. It would be desirable that every college for young men and women should have compulsory instruction on the influences of heredity. Every young man and woman should know the dire consequences to the offspring resulting from a tainted strain; every young individual should know that not only syphilis but many of the physical and nervous evidences of the stigmata of degeneration might be transmitted to the offspring; they should know that a clear descent only was obtainable from a clean strain. Every young individual should be instructed upon the general principles of the rights of the newborn—they should be made to recognize the principle that altruism should govern the selection of a mate; that, as one young man argued to him, his parents did not consider his inheritable possibilities, why should he consider the questionable attributes of his possible children, was the height of sophistry. It was an utopian dream, but it would be well if it were possible to curtail the mating of the misfits. Sterilization of the criminal insane, the moron, the epileptic, was a problem for the future. The legislative control of marriages of those afflicted with inheritable disease, requiring a medical certificate from one or both parties was theoretically correct—in practice was of questionable value. At the present time control of mental defectives, those afflicted with transmissible taints which might mar the mate or the young was too abhorrent to the yet uneducated mind. Coordinated to instruction given to the young in college, even high schools, it would be well to have systematic courses of instruction to young men and women who could not secure a higher education. Conferences should be held covering the general problem of eugenics; suggestive courses should be given to prospective mothers and to young fathers, that they might meet their responsibilities with intelligence and knowledge.

2. He would have a properly equipped maternity hospital with divisions covering the various needs of the prospective mother, her child before and after its advent into the world. He doubted the expediency of having independent centers for the prospective mother, for her confinement, and for the infant welfare. A properly coordinated whole under one efficient head would bring about more ideal results than haphazard attempt at conservation. Such an ideal center would comprise these divisions: (*a*) A social investigator who should visit the home and determine the true eco-

nomic need of the family. If the family had a certain degree of affluence they should be directed to approved, enthusiastic young practitioners who had the heart and conscience to carry on the truths of conservation for a stipend. Such physicians in an emergency could call upon the staff of the institution for aid or advice. (*b*) Opportunity and encouragement should be given to all prospective mothers to avail themselves of the antenatal clinics. At stated hours each day a corps of young physicians should be attendant so that periodic examinations, physical as well as those of urinalysis might be carried out; at the same time general hygienic rules might be formulated for the individual. As one-half of the crises incident to the unborn were more or less preventable, here was the first step to the conservation of infant life. (*c*) At the time of labor the record of the patient should be transferred, or at least made available to the maternity department. The personnel of this department should be imbued with the responsibility of the task; they should have an obstetric conscience; they should have a love for the work and an enthusiasm which would prompt them to sacrifice self in the need of the patients. Parenthetically an administrative body of physicians should have the control of policy, of expediency, that no man might become a fadist or an extremist without check. This department should control the care of the woman and her child until discharged from the institution. (*d*) Every woman, before leaving the maternity, should receive positive instructions for her return for a postpartum examination—for recommendations for her own welfare. (*e*) An infant welfare department where periodically the baby might be brought for weighing and advice; where it might be brought if ill. In conjunction with this department there should be an adequate department for the preparation of foods for infants. (*f*) Systematic courses of lectures should be instituted covering all the phases entering into the questions of personal hygiene, marriage relations, matters cognate to bearing of children, the care of women in pregnancy, and the care of children thereafter.

Syphilis and Its Relation to Infant Mortality.—Dr. P. C. JEANS of St. Louis said that when conception had taken place, the effect of maternal infection upon the product of conception was dependent to a large extent upon the duration of the pregnancy at the time of fetal infection. The infection of the germ cell, if such an event ever occurred, would preclude the possibility of its further development. The earlier in pregnancy the infection of the fetus, the more likely was pregnancy to terminate in a dead or non-viable infant. The birth of a viable syphilitic infant signified its infection late in pregnancy. The time at which fetal infection occurred was dependent upon the activity of the infection in the mother, and this in turn was dependent to a large extent upon the time elapsed since the onset of her infection. In many instances in untreated mothers pregnancies occurring ten years or more after the infection of the mother had resulted in the birth of nonsyphilitic children. It had become a well recognized fact that syphilis was the largest single cause of death of the fetus at or before term. Stillbirths had averaged in the neighborhood of five per cent. of all births wherever studied, and at least one-third of this number was due to syphilis. A compilation of statistics showed that of 4148 pregnancies in syphilitic families, 1258 or 30 per cent. resulted in the death of the fetus at or before term. That this was more than three times greater than what might be considered the normal waste of life at this early age was shown by a similar study among the poorer class in both St. Louis and London, and including no obvious syphilis. In St. Louis 9.9 per cent. of 886 pregnancies and in London, 9.4 per cent. of 826 pregnancies resulted in the death of the fetus at or before term. Though there might be some doubt as to syphilis being a frequent cause of sterility, there was no doubt that it was a fairly frequent cause of childless marriages. Adair stated that of 50 premature infants observed in Minneapolis, 9 or 18 per cent. were proven syphilitic. Prematurity occurred but 8 times in 886 pregnancies in 200 St. Louis families in which there was no obvious syphilis, while it occurred 10 times in 453 pregnancies in 100 syphilitic families, showing an incidence 2½ times greater in syphilitic than in non-syphilitic families, and indicating that syphilis was the most frequent cause of this event. The mortality among premature infants was relatively high whether with or without syphilis. When the problem of maintaining the nutrition and body heat of a prematutre infant was added to by a syphilitic infection, the outcome was much less hopeful. There was in the literature a scarcity of statistical studies bearing on the incidence of syphilis in the infant population of this country. Because of the high mortality connected with syphilis in infancy, the group studies among older children or among groups containing older children gave an incidence much lower than was to be found in infancy. In St. Louis clinical study was made of 854 infants of one or under, and Wassermann reactions were made on all infants whose family history, personal history or examination gave any suspicion of syphilis. Of the 854 infants studied, 42 or 4.9 per cent. were found to be syphilitic. This figure represented the minimum in this group because it was not a complete Wassermann survey. In New York Holt found 6.2 per cent. positive Wassermann reactions among 161 infants under 2 years of age. Holt's series was selected to the extent that it contained no clinical syphilis, but did contain a certain number of infants whose history or examination gave a suspicion of syphilis. Commisky reported 3.2 per cent. positive Wassermann reactions in 1074 new-born babies in Brooklyn. Because of the frequency of a negative Wassermann reaction in a syphilitic new-born baby, such a study, though interesting, did not represent the true incidence of syphilis. It would seem safe to assume an incidence of about 5 per cent. for syphilis in our infant population. Perhaps of equal interest in this connection was the proportion of the pregnancies in syphylitic families that resulted in living non-syphilitic children. Among 2450 pregnancies of his own and collected cases 408 or 16.6 per cent. resulted in children who were living at the time of the study and found to be non-syphilitic. This was but slightly more than one-fifth of the healthy living children to be found in a similar study among an equal number of pregnancies in non-syphilitic families. A survey of about 300 syphilitic families in which there occurred 1366 living births showed that 30 per cent. of these infants died at an early age. Since syphilis was the only known factor of difference between these two groups it would seem that the infant with syphilis had just half the expectation of life as did a non-syphilitic infant, leaving out of consideration all other factors. The prognosis in a syphilitic infant depended upon several factors, including the severity of the infection, the type of feeding, and the state of nutrition. From 10 to 20 per cent. of adult males and about 10 per cent. of married women were syphilitic, and a minimum of 10 per cent. of marriages involved a syphilitic individual. Seventy-five per cent. of all the offspring in a syphilitic family were infected. In a syphilitic family 30 per cent. of the pregnancies terminated in death at or before term, a waste three times greater than was found in non-syphilitic families. Thirty per cent. of all the living births in a syphilitic family died in infancy as compared to a normal rate of 15 per cent. in the same class. Probably 30 per cent. of clinically syphilitic infants died as a result of syphilis. But 17 per cent. of all the pregnancies in syphilitic families resulted in living non-syphilitic children which survived the period of infancy. About 5 per cent. of our infant population was syphilitic. According to St. Louis vital statistics 3½ per cent. of all infants' deaths were ascribed to lues.

The Springs of a Nation's Life.—Dr. EDWARD P. DAVIS of Philadelphia stated that to secure a healthy infant population it was absolutely essential that the conditions of life be such that early marriage could be encouraged. A living wage, sanitary and comfortable means of dwelling, civic sanitation, including a pure and reasonable food supply, and all those agencies which made for physical, mental and moral hygiene were of the utmost importance. A new responsibility was placed upon civic authorities, and more than ever was there imperative need for civic righteousness in the administration of civic affairs. From the standpoint of efficiency only, the great corporations were realizing the necessity for caring for the individual worker. Genuine philanthropy reached its highest and most intelligent

expression in this accomplishment. Some corporations employed skilled medical service, constructed hygienic dwellings, encouraged insurance and educated in matters pertaining to health, and not only gave a living wage, but taught those who worked with them and for them, how to live. No greater curse upon the nation in the care of its infant population could be devised than the presence of a large standing army. It was a fact familiar to all who had lived in continental Europe that marriage was forbidden to men of military age unless they possessed a certain stipend. The result was indiscriminate immorality, and in order to save its population the state was obliged to care for the mothers in hospitals and to rear the children in foundling asylums. The mortality percentage among infants so reared was notoriously high, and the effect produced upon pregnancy and parturient women was most injurious. Whatever might be the military necessity of the future, the people of these United States should take warning, and under no circumstances saddle themselves with a large and permanent standing army. But the crying need in the prevention of infant mortality was better obstetrics. It was true that in order to make improvement in obstetrics possible the economic and other factors to which reference had been made must be present, but it was also true that without better obstetrics these factors would be of little value. The encouragement of early marriage in sound individuals was a step of primary importance; marriage among those physically unfit was to be discouraged and, if possible, forbidden. It might not yet be possible to require physical examination of men and women before marriage, but certainly the need for such was evident. Education of the laity, nurses, and doctors in matters concerning the increase and care of the population was of paramount importance. The difference between prudery and honest pride in what was natural, and in itself beautiful, must be made evident.

The medical profession in Europe and the United States had for years been spreading abroad among women concise statements concerning the first symptoms of cancer. A brief description in simple language of its symptoms had been posted in rooms frequented by women only, upon the Continent and in some places in this country. Why should not a similar brief, clear statement of symptoms of dangerous conditions arising in pregnant women be posted in the rooms used only by women throughout the country? Why should not attention of expectant mothers be called to the dangers of miscarriage and convulsions and hemorrhage occurring during pregnancy? Much had been done to educate medical students and physicians for better obstetrics, but economic conditions and lack of hospital facilities had been such that doctors could not afford to do, in a large private practice, the careful work accomplished in good hospitals. At present there had been great improvement in many States of the Union, license to practise was refused to those students who had not had a fair obstetric experience. The multiplication of hospitals, the opening of maternity wards, the fact that patients resorted to hospitals for confinement, better knowledge of obstetrics, and, above all, the recent developments in obstetric surgery, had been great advances, and yet today there were three great dangers which threatened tthe physical life of women in the child-bearing age, tuberculosis, cancer, and parturition, and this condition was the result of the fact that in the so-called private practice of obstetrics, as indiscriminately carried on by the general practitioners, there was very much to be desired. The modern obstetric trained nurse had saved the lives of thousands of infants. So splendid was the profession of nursing that it was difficult to select one field more brilliant in results than another, but if life and health and happiness and joy of families were appreciated, then the well trained obstetric nurse had won great achievements. The trained nurse had made the modern hospital a safe refuge for the poor mother. The antiseptic precautions taken in such hospitals had eliminated to a large extent the greatest dangers of parturition. Maternity hospitals should contain a considerable number of beds devoted to pregnant patients only. Parental care he recognized as most important in the interest of mother and child. Pregnant women who were ill required hospital care and life and health were saved in a surprisingly large percentage by such protection.

How to Conduct a Survey in the Interest of Child Welfare Work.—Miss PANSY V. BESOM of Boston said that the most important factors in child conservation were parental care, obstetrical care and infant feeding. The committee felt that this survey would disclose the fact that deaths in early life were due to the failure of people to secure proper care in these fields of medical work. It was assumed that the well-to-do would always be in a position to secure competent, continuous medical care. So provision must be made for the rest of society to conserve life and thus increase our man power. A public health nurse was appointed for each health district in the state, and an additional nurse for Boston. These nurses were selected with the greatest care, and all of them had had not only public health training but a considerable amount of experience in actual public health field work for children. In making the surveys the nurses had visited the representatives of the boards of health, the child welfare agencies, the visiting nursing associations and other private or church organizations which were doing child welfare work. Positions had been created for forty-six nurses as a result of the movement, while thirty child welfare stations and eight prenatal clinics had come into existence.

The Home Care of the Infant.—Miss F. E. BISWANGER of Philadelphia said that at birth the infant's mouth and eyes should be cleansed with boric acid solution; the child turned upon its right side, so that its heart valve might properly close, and the child should be thoroughly but gently rubbed with warm olive oil. A warm sponge bath and the clothing of the infant in woolen abdominal band, woolen shirt, diaper and flannel slip would make it comfortable and it would rest and sleep. The new-born child should not be disturbed by friends or relatives. The secret of its comfort in its food and sleep lay in absolute regularity and freedom from disturbances. For good digestion the infant's mouth should be gently but thoroughly cleansed with boric acid solution before feeding. Water in addition to its food should be given at regular intervals by the use of a bottle and rubber nipple. Every effort must be made to favor the nursing of the infant. In cases where the first milk was too fat and disagreed it might be removed by the breast pump with very gentle pressure, and the child given the less fat milk which came after. Where the milk was thin and deficient, the attention of the physician must be called to this fact, and under his supervision suitable diet and perhaps tonics might be used. The first essential in artificial feeding was the cleanest and best milk available; the second essential, minute and written directions from the physician, and on the part of the nurse; the accurate measurement of the different ingredients of the child's bottle and the accurate carrying out of the physician's directions.

The Importance of Prenatal Care.—Dr. LIDA STEWART COGILL of Philadelphia read a paper on this subject, based upon experience at the Woman's Medical College of Pennsylvania, its hospital, the Woman's Hospital of Philadelphia, and the West Philadelphia Hospital for Women. She summarized as follows: "(1) More uniform and higher standard of obstetrical teaching in medical colleges with greater attention to the subject of prenatal care. (2) Establishing of a greater number of prenatal clinics and health centers. (3) Establishment of health clinics for mothers of child-bearing age." Child welfare workers were better able to cope with conditions affecting the life of babies from one year up to school age than they were with the prenatal conditions affecting mothers and the infants up to one year of life and they were calling for assistance and advice in remedying this defect. The Woman's Medical College of Pennsylvania was one of the first to realize the importance of instruction to students on the importance of prenatal care. The objects of the postnatal clinic were: (1) To have complete obstetrical record of mother and child from beginning of pregnancy to end of puerprium, eight weeks. (2) Questions as asked by the Babies' Welfare Association as to how many babies living and breast fed at

end of first month could be more easily ascertained. (3) Pelvic condition of mother could be watched and patient referred to another clinic for further treatment when needed. (4) Making of a stepping stone to the establishment of a mother's health clinic, thus overcoming that stage of neglect among mothers of child bearing age. (5) Help save those 15,000 mothers who die needlessly each year and that 80 per cent. of babies who perish before the first month of life.

The City Nurse as an Agent for the Prevention of Infant Mortality.—Dr. HARRIET L. HARTLEY of Philadelphia stated that in the matter of determining with some degree of accuracy the health of a given district or locality, we had no better or more intelligent surveyor than the city nurse. Her experience had brought her in contact with all kinds and conditions of men, her method of approach to the keeper of the home, usually the mother, was one which bred friendliness and confidence, and an understanding of the true condition of the home and its inmates was arrived at from a standard viewpoint with a minimum waste of time. The city nurse with her general training as a nurse knew the earmarks of disease. As a public health nurse she readily recognized poverty, destitution and alcoholism. She could judge whether the family income was large enough or expended in such a way as to insure the proper amount of health and comfort to the family.

Her connection with the board of health made her an authorized sanitary inspector and her general knowledge of the principles of housing and sanitation made her a good judge of the conditions surrounding the young infant. She could intelligently observe the care of the food, the refrigerator, utensils, etc., which either intimately or remotely affected the health of the baby. Here also brought into use her knowledge of ventilation and readily determined whether the baby got the proper ventilation to guard it against respiratory disease. In prenatal work the city nurse had no peer. The expectant mother was much more apt to confide in the nurse who gave advice about babies than she was any other type of health worker. The nurse often learned of the pregnancy early in its history, became the mother's friend and confidant and led her in the direction she should go.

The Work of the Training School of the Philadelphia General Hospital in Preventing Infant Mortality.—Miss BLANCHE SOULE of Philadelphia said that the Social Service Department took care of the prenatal work outside the hospital, and a great deal of prenatal work was done in the obstetrical department. The social service worker found the expectant mother, endeavored to gain her confidence and interest and impressed upon her the importance of medical care during her pregnancy. She was then directed to the prenatal clinic and at the same time the patient's name, address and a short history, home conditions, etc., were sent to the clinic. If the patient did not visit the clinic as she promised, the clinic found out why she had not come and looked after her. The Maternity Department was made up of two distinct departments, one for the clean patients and the other for venereal patients. In the clean maternity wards during the past year they had not had one case of toxemia in the patients who were under their care several months before delivery. In the Venereal Maternity Ward they had one case of toxemia in a patient who was admitted when eight months pregnant. In the Children's Department they had the same division as in the Maternity Department for the clean and the infectious patients. The vaginitis patients had a separate floor of the hospital. The doctors and nurses taking care of these children did not come in contact with children in any other part of the hospital. There was separate clothing for this department and all diapers were burned. In the work of prevention, the obstetrician, the pediatrician, and the nurse must work together with one common aim. She believed that if the nurse would accomplish the most good in this great preventive work she must be thoroughly prepared for it. She had lectures in obstetrics and pediatrics and classes in these subjects, attended clinics and did follow-up work on the wards.

Problems of Infant and Maternal Welfare in Rural Communities.—Miss KATHERINE M. OLMSTED of Chicago stated that the existence or the development of a well and a broadly organized public health nursing section in every State health department was the first and the most important need in any movement for better care of our rural health conditions. The obligation of this department should be: (1) To stimulate local county demand for public health nursing service and secure public funds for maintenance of work in counties. (2) To provide well trained competent nurses to meet the demand. This condition was improving. The work of the national association was being felt. (3) To coordinate and supervise the work of all the nurses throughout the State, much as was done with the county health officers now, with a view to standardizing fundamentals and stimulate the tendency toward a higher type of public health nursing in rural sections. The speaker firmly believed that were each State provided with such a department and each of these departments provided with an extremely efficient, well trained, widely experienced, supervising nurse within a few years most of the counties in all of our States would have efficient public health nursing services. The services of a State supervising nurse were varied; among them were (1) to enlighten the communities about the value of the service, the duties of the nurse and methods of adequately financing the work. (2) To assist each nurse in adapting herself to the specific demands of the community. (3) To visit the nurses and give advice and training. (4) To conduct through correspondence a library department for encouragement and stimulation toward better work. (5) To arrange with universities and schools within the State, courses for beginners and institutes for older workers in public health nursing.

Rural Work for Infant Welfare in Canada and Other Countries.—Dr. MAURICE MACDONALD SEYMOUR of Regina, Saskatchewan, in summing up the work undertaken in the different provinces of Canada, in the effort to reduce infant death rates in the rural districts, said the following were the important methods employed: (1) The establishment of municipal hospitals subsidized by the government at rural points. (2) The appointment of medical men at a salary by municipal councils, to serve the rural communities. (3) The conducting of child welfare clinics and exhibits, lectures, etc., at rural centers, more particularly in connection with fairs, when most publicity could be secured. (4) Wide distribution of literature dealing with care of the baby. (5) The adoption of a system of rural public health nursing which would be greatly increased in the near future. (6) Government maternity grant to expectant needy mothers in rural districts. (7) Education of the public and wide distribution of literature on the subject of infectious diseases, particularly with regard to the venereal diseases. In order to improve the situation the adoption of the following measures was to be strongly recommended: (1) A system of dominion-wide training, registration and thorough supervision of midwives. (2) A general system of rural public health nursing, with particular reference to child welfare and prenatal care. (3) The providing of free treatment for all syphilitics by means of cooperation between government and municipal authorities. (4) A more general provision for government aid for maternity cases.

Adequate Reproduction.—Professor ROSWELL H. JOHNSON of the University of Pittsburgh said that for any country, at any given stage of advancement of its arts and of exhaustion of its resources, there was an optimum number of inhabitants up to which the country could continue its population without producing an undue pressure upon subsistence. Above this optimum the number was such as to lead to injurious poverty regardless of faults of distribution. A well ordered community would strive to reach this adjustment. It might do so by encouraging or discouraging immigration, encouraging or discouraging emigration, or by raising or lowering the birth rate. General welfare demanded a mimimum death rate and a marriage rate limited only by considerations of the unfitness of the parents, so that neither should be modified for population considerations. Only the birth and migration rates might be modified for this purpose. There was little reason to believe that any large part of the world was especially not our own country. There seemed to be no cause for increasing our population, and

we needed to be concerned only in maintaining our population, which we were already doing. But so far we had considered the population as a whole. When measured it was found to consist of persons of widely varying individual and social worth. Our population was made up of a large number of those of middling value, with the proportion of persons above and below this middle average constantly diminishing as the deviation from the average increased. These differences in the value of the individual to society were known to be in large part inherited. It became of great moment to know the relative birth rate of the several sections. Obviously racial progress depended on a disparity in the reproduction of these groups in one direction. If reproduction of the most inferior was prevented, as should be done, then the remainder must yield to a higher birth rate. But in addition to that the superior half should have a higher rate than the inferior half. Professor Sprague of the Massachusetts Agricultural College found 3.7 births were necessary to sustain a fixed population. Hence we must expect more than 3.7 births from all superior women or we could not have a progressive race and maintain our numbers. There was then a racial *noblesse oblige*. Unfortunately it found little recognition, for there was abroad a spirit of misguided selfishness cloaking itself in fine phrases "realizing one's capacities," "being true to oneself," "following one's bent." The modern superior celibate, heedless of the future, set up these false gods. Woe to the nation which, like ours, found its superior women slacking on the job of motherhood, as ours were doing.

Election of Officers.—The following officers were elected: *President*, Dr. S. Josephine Baker of New York; *President-Elect*, Dr. Phillip Van Ingen of New York; *First Vice-President*, Dr. William Parker Lucas of San Francisco; *Second Vice-President*, Dr. N. S. Rankin of Raleigh, N. C.; *Secretary*, Dr. Henry F. Helmholz of Evanston, Ill.; *Treasurer*, Mr. Austin McLanahan of Baltimore; *Executive Secretary*, Miss Gertrude B. Knipp of Baltimore.

NEW YORK ACADEMY OF MEDICINE.

Anniversary Meeting, Held December 5, 1918.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

The Biology of Democracy.—Professor EDWIN C. CONKLIN of Princeton University delivered this address, in which he stated that the war which had just closed was begun by autocracy and militarism for personal and national aggrandizement. It had ended in victory for those who had entered it to make the world safe for democracy. The world had been made not only safe for democracy, but unsafe for anything else. Many German scientists as well as military men had claimed the sanction of science and especially of biology for the beneficial effects of war, for a militarized state, and for an hereditary aristocracy. If democracy was to endure and prevail it must rest upon science as well as sentiment. It might therefore be profitable on this occasion in addressing members of the greatest of the biological professions to examine certain aspects of democracy in the light of biology, for undoubtedly the principles of biology applied to man and his institutions no less than to other organisms. There were three main lines of evolution—the physical, the mental, and the social. Of these the physical was the most visible, the intellectual the most rational, and the social the most ethical. These three were not antagonistic to each other, as Huxley thought.

The speaker then discussed the biological bases of democracy, stating that there were many kinds of democracies in many fields of human activity; for example, in government, industry, commerce, education, etc., and it was difficult to define the exact meaning of the term, but it would be admitted, he thought, that democracy in its widest sense meant the ultimate control of all matters of common interest by the people as a whole rather than by any person or class. The rights of man as man had ever been the foundation stones of democracies. Our Declaration of Independence and the motto of France, "Liberty, Fraternity, Equality," represented in many respects the fundamental ideals of democracy. Questions of great biological and social importance were these: How could we have individual liberty together with social organization and harmony, universal fraternity in spite of national and class antagonisms, democratic equality in spite of inherited inequalities?

1. *Individual Liberty vs. Social Organization.*—Was the ideal state one in which the social bond was as loose as possible and individual freedom was the chief aim, or was it one in which the bond was as close as possible and the good of the nation or race or species was the supreme object? There could be no question as to the biological answer. The whole course of evolution from amoeba to man was marked by increasing specialization or limitation of constituent parts of an organism and their integration and cooperation in the organism as a whole. Nature invariably sacrificed the individual, if necessary, for the good of the colony or race or species. If democracy means decreasing specialization and greater personal freedom it was doomed to disintegration and extinction. But democracy did not necessarily mean this. It was only our experience as a pioneer society, where every person could be a self-sustaining unit, that led to this conclusion. As a country became more populous greater specialization and limitation of individuals and greater cooperation and harmony among them were essential. The freedom of the individual must more and more be merged in the larger freedom of society. Democratic freedom must of necessity mean the freedom of society rather than that of the individual.

2. *Universal Fraternity vs. National and Class Hostility.*—Biology proved that we were all cousins if not brothers. If the number of our ancestors doubled in each ascending generation, as would be the case except for the marriage of cousins of various degrees, each of us would have had more than one billion ancestors one thousand years ago, say in the reign of William the Conqueror. Even allowing for numerous intermarriages of relatives it was highly probable that all people of English, French or German stock were descended from the same ancestors of a thousand years ago. All of us were literally descendants of royalty and of any and every other person of one thousand years ago who left many descendants, including nonentities and worse. We hunted up our noble ancestors and forgot the others. In length of descent we were all equal and in community of descent we were all cousins if not brothers. As a result of this common descent human resemblances were vastly more numerous and important than the differences. Racial and varietal differences represented a natural classification based chiefly upon physical characteristics and these differences tended to cause a natural and desirable segregation of races, but they did not justify racial antagonisms. The fundamental social instincts of all races were so essentially similar that all might and often did live together in harmony; and the cooperation of all types of men in organized society was so much a matter of education and environment that the most distinct races might work together in mutual helpfulness. When we come to those minor subdivisions represented by various European stocks the distinctions were usually so slight that they formed no natural barrier to the most intimate association and cooperation, as we had abundantly demonstrated in this country. The inherent antagonisms between these stocks that agitators and designing politicians told us about were really not inherent at all but were largely created, cultivated, and magnified for national and selfish purposes. The biologist must look with concern upon the breaking up of European nations into minor independent units, just as the intelligent American would deprecate the breaking up of our own country along similar lines. Such a process represented disintegration and devolution rather than progress and evolution. When we come to those minor class distinctions based upon occupation, wealth, or social position we had the most artificial and unnatural classification of all. This was not to say that persons should not associate in congenial groups which had common interests and ideals; but when attempts were made to array one group against another and to make these classes permanent and hereditary, an artificial disharmony was introduced into society which could work only disastrously. Autocratic personal or class rule was always bad, for no person or class was wise or

good enough to rule other persons or classes without their consent. The strength and stability of governments were proportional to their all inclusiveness, their breadth of base, whereas autocracies were inverted pyramids. Equal universal suffrage and majority rule were the only self-preserving mechanisms yet discovered for harmonizing conflicting elements in a population; they were the safety valves of society. Majority rule would level society down to general mediocrity were it not for the instinct of the people to follow leaders. Neither in a democracy nor in an autocracy did the people make the plans for the form of government, for war or peace, or for anything else. These plans were always made by leaders, but in one case they were laid before the people for approval or disapproval and in the other they were not.

The greatest danger that confronted democracy was not its slowness and inefficiency but the fact that unscrupulous leaders might pervert and misdirect the normal social instincts of the people in order to accomplish selfish and partisan purposes. The only remedy for this great danger was that the people as a whole should be educated to appreciate the difference between emotional and rational appeals.

3. *Democratic Equality vs. Hereditary Inequality.*—Our democratic creed was that "all men are created equal," and yet nothing was more evident than that men were unequal in personality, intellect, and influence, and biology showed that many of these inequalities were inherited. How should we harmonize the teachings of biology with those of democracy? Hereditary aristocracy was founded upon an obsolete idea of inheritance, namely, "the law of entail;" it confused social and biological heredity. A son might inherit the property of his father in its entirety, but not his personality; his titles and privileges, but not his intellect and character. In biological heredity the qualities of the parents were separated and redistributed to the offspring so that the latter were "mosaics" of ancestral traits. The best traits might appear in parents and be lost in their children. This was the great law of heredity discovered by Mendel and it differed fundamentally from the law of entail. The law of entail was aristocratic but the law of Mendel was democratic. No family had a monopoly of good or bad traits and no social system could afford to ignore the great personalities that might appear in obscure families or to exalt nonentities to leadership because they belonged to great families. Democracy did not mean that all men were equal in personality. It was not a denial of personal inequalities but the only genuine recognition of them. Rigid class and family distinctions, on the other hand, were denials of individual distinctions. It did mean equality before the law, no special privileges due merely to birth, freedom to find one's own work and place in society. In short, it meant that every man was to be measured by his own merits and not by the merits of some ancestor whose good qualities might have passed to a collateral line. Democracy alone permits a natural classification of men with respect to social value, and it contributed more than any other system of government to the contentment, peace, and stability of the peoples of the world.

THIRD RESUSCITATION COMMISSION.*

Meeting Held in New York at the Rockefeller Institute, Friday, May 17, 1918.

Chairman's Address.—Dr. S. J. MELTZER of New York said that the object of the commission was to consider efficient methods of artificial respiration in emergency cases, as they were met with in peace as well as in war. For more than a century England had had several life-saving societies, and many special commissions had been appointed to investigate the methods employed in resuscitation. In this country, about six years ago, a Commission on Resuscitation from Electric Shock was created for the first time by the initiative of the National Electric Light Association. It was now generally recognized that efficient artificial respiration was, for such conditions, the best and practically the only means available for resuscitation. It required but little consideration to realize that the need for an efficient means of artificial respiration was very widespread. For instance, in injuries to the head which stopped respiration, injuries to the chest (especially double pneumothorax) in laparotomies during which the respiration ceased occasionally, in cases of shock which occurred in peace and more so in the present war, in poliomyelitis with stoppage of respiration, in postdiphtheric paralysis, in poisoning by opiates, by volatile gases (ether, chloroform, etc.), by mine and fuel gases, poisoning by magnesium salts, in electric shock, and in drowning.

Mechanical Methods.—Dr. MELTZER demonstrated in the laboratory for physiology and pharmacology the efficiency of the method of pharyngeal insufflation in an etherized dog after complete removal of the anterior wall of the thorax, in which the lungs and heart were exposed to full view.

Dr. ROSSITER of the Carnegie Steel Company demonstrated the latest device of the Pulmotor Company, which was not identical with the original pulmotor. He showed also the original pulmotor. He stated that he had resuscitated eight patients asphyxiated by gas in whom respiration had stopped. This was done by the original pulmotor in which he had more confidence.

Dr. JAMES M. BOOHER, Medical Director of the Life Saving Devices Co., demonstrated the lungmotor. He showed a number of bloodpressure tracings, taken from animals which had received artificial respiration by means of this apparatus. In reply to a question he stated that in these experiments the lungmotor was connected with the animal by means of a tracheal cannula. In human cases it was applied by means of a face mask. Dr. Booher left with the commission histories of a number of cases in which the lungmotor had been used. The commission found no time to examine these written histories, but Dr. Booher reported especially two cases. One of these was subsequently investigated by the chairman. The life of a poliomyelitis patient with complete paralysis of the respiration was maintained for thirty-six hours by means of the lungmotor.

Mr. FOREGGER demonstrated an apparatus which was a modification of the insufflation apparatus of Meltzer. Among other changes the apparatus carried an oxygen generator tank. In reply to a question Mr. Foregger stated that the oxygen thus generated might last eight or ten minutes.

Manual Methods.—Mr. EGLIN read a letter from Mr. M. W. Alexander of the General Electric Co., stating that he hoped the "commission would be very definite in recommending the prone-pressure method, as experience has proved its value."

Mr. C. B. SCOTT stated that the Accident Prevention Committee of the N. E. L. A. had reached the point in its investigation where it felt that the prone-pressure method was best to recommend, bearing in mind that machines were not always available in emergencies. His own company had had nine successful cases of resuscitation by the prone method and three unsuccessful cases in which mechanical means were used.

Dr. SCHUBMEHL stated that the prone-pressure method had been most successfully applied by their two hundred and twenty-five first-aid men.

Mr. MACLACHLAN stated that he had the duty of training possibly three thousand men in the prone method. Their system required the men to practise this method at least once a month. The men were instructed not to desist in less than three and a half hours, and that not till then should they listen to advice from a physician who might tell the operator that the patient was dead.

The secretary read the following parts of a letter from Professor Schäfer of Edinburgh to the chairman: "The prone method has been adopted *exclusively* for about twelve years by the Royal Life Saving Society, the only important organization in the British Empire whose object is the resuscitation of the apparently drowned. It has also been adopted for several years by the London and other police forces, by the Board of Trade, by the Army and the Navy. The most important thing is in cases of drowning to have something ready which any man can use; which will effect

*Under the auspices of the Committee on Safety Rules and Accident Prevention of the National Electric Light Association.

respiratory exchange—whether exactly as much as normal matters very little."

In the discussion following the presentation of methods and evidence to the commission the following facts were emphasized: (1) That in most accident cases no resuscitation apparatus was at hand for immediate use. (2) That reliance upon the use of special apparatus diminished greatly the tendency to train persons in the manual methods and discouraged the prompt and persevering use of such methods. (3). That police officers or physicians often intereferd with the proper execution of manual methods, in that they directed that the patient be removed in an ambulance to some hospital, thus interrupting the continuance of artificial respiration. (4) That in many hospitals the members of the staff were not all acquainted with the methods of artificial respiration. (5) That in medical schools instruction was not properly provided for students in the manual methods of artificial respiration.

Resolutions.—In view of these facts the following resolutions were adopted by the commission:

"1. The prone-pressure or Schäfer method of resuscitation is preferable to any of the other manual methods.

"2. Medical schools, hospitals, fire and police departments, the Army and Navy, first aid associations, and industrial establishments in general should be urged to give instruction in the use of the prone-pressure method of resuscitation.

"3. Individuals who, from accident or any other cause, are in need of artificial respiration, should be given manual treatment by the prone-pressure method immediately on the spot where they are found. It is all important that this aid be rendered at once. The delay incident to removal to a hospital or elsewhere may be fatal, and is justifiable only where there is no one at hand competent to give artificial respiration. If complications exist or arise which require hospital treatment, artificial respiration should be maintained in transit and after arrival at the hospital, until spontaneous respirations begin.

"4. Persons receiving artificial respiration should, as much as possible, be kept warm and the artificial respiration should be maintained till spontaneous breathing has been permanently restored, or as long as signs of life are present. Even in cases where there is no sign of returning animation artificial respiration should be kept up for an hour or more.

"5. A brief return of spontaneous respiration is not a certain indication for terminating the treatment. Not infrequently the patient, after a temporary recovery of respiration, stops breathing again. The patient must be watched, and if normal breathing stops the artificial respiration should be resumed at once.

"6. Artificial respiration is required only when natural respiration has ceased. In cases of simple unconsciousness from any cause in which natural respiration continues, artificial respiration should not be employed without medical advice.

"7. The commission recommends that in cases of gas asphyxiation artificial respiration, whether given by a manual method or by special apparatus, should be combined when possible with the inhalation of oxygen from properly constructed apparatus.

"8. With regard to the employment of mechanical devices for artificial respiration the commission feels that it ought not at present to take a definite stand either for or against any particular form of apparatus. However, the commission recommends that the use and installation of apparatus should be confined, for the present, to properly equipped institutions under medical direction. The commission recognizes the great need of simple devices capable of performing artificial respiration reliably and efficiently. It therefore recommends a careful study of the problem, directed toward the *development of a reliable method appropriate for general adoption.* Such studies can best be carried on in properly equipped hospitals and laboratories which offer opportunities and facilities for critical observation and experimentation."

Dr. YANDELL HENDERSON presented a minority report dissenting from the statement in resolution 8 recognizing "the great need of simple devices capable of performing artificial respiration reliably and efficiently." "Devices which are excellent from the mechanical standpoint," he said, "are now available and widely sold; but the evidence regarding them indicates clearly that even if these devices were on the spot where several gassings or electrocutions occurred, and if all the victims were treated with them, except one who was given manual (prone pressure) treatment, this one would have much the best chance of recovery. In actual practice the apparatus is seldom right on the spot adjusted and ready. Critical time is lost, and thus in the above suppositious cases, as they actually occur, the only victim with any considerable chance of resuscitation (aside from those who recover spontaneously and are credited to the apparatus) is the one treated manually. Even more important is the fact, demonstrated now by universal experience, that when apparatus is known to be obtainable it is sent for and the manual method neglected. Thus to-day the apparatus in public use is on the whole contributing very materially to decrease the saving of life."

Recommendations.—"In view of the importance which the knowledge of proper methods of resucitation possesses for public health and safety, and considering the fact that many practitioners, members of hospital staffs, and graduates of medicine are not thoroughly familiar with the methods of resuscitation, especially that of the prone-pressure method, the commission recommends: (*a*) *That medical journals* (and other scientific and practical journals which are interested in the problem of resuscitation) *be asked to publish the resolutions adopted by the commission.* (*b*) *That a copy of these resolutions be sent to the medical colleges with a request that proper instruction in this subject* shall be arranged for in the college schedules. (*c*) That these resolutions be sent to as many hospitals as possible, with the recommendations that members of the house staff shall familiarize themselves with the methods of resuscitation. (*d*) In order that the resolutions of the commission may be brought to the attention of interested circles (fire and police departments, industrial plants, etc.) it is agreed that they be communicated to the Associated Press by the National Electric Light Association.

It was voted that the Third Resuscitation Commission should be properly organized and continue its existence, ready to respond when requirements arise.

Officers.—The following officers were elected: *President*, Dr. S. J. Meltzer; *Vice-President*, Dr. Yandell Henderson; *Secretary*, Dr. Reid Hunt; *Treasurer*, Mr. W. C. L. Eglin.

It was voted to appoint a committee for the collection of verifiable data relating to resuscitation. The president appointed to the committee Dr. D. Edsall, chairman; Dr. Reid Hunt, secretary; Prof. Elihu Thomson, and the president ex-officio.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

PRACTICAL PHYSIOLOGICAL CHEMISTRY. By PHILIP B. HAWK, M.S., Ph.D. Sixth Edition. 661 pages. Illustrated. Price, $3.50. Published by P. Blakiston's Son & Company, Philadelphia.

THE HUMAN MACHINE AND INDUSTRIAL EFFICIENCY. By FREDERIC S. LEE. 119 pages. Illustrated. Price, $1.10. Published by Longmans, Green & Company, New York.

INDEX.

A

Abdomen, contusions of the, diagnosis and treatment of, 520; traumatic, avoidable, 259, 695.

Abdominal disorders, the diagnostic value of pain in, 639; inflammations, acute, study of diaphragmatic movements in, 41, 348; viscera, fatal injuries of the, in the new born, 429.

Abducens paralysis, complicating mastoiditis, a case of; brief discussion of this complication as an indication for surgical treatment, 941.

Abortions, induced, causing sterilization, pathological conditions of the pelvic viscera, the result of, 961.

Abrams, Albert, a new method of percussion, 853; a new test of heart function, 680; the stigmata of Abrams in hereditary syphilis, 101.

Abscess, bronchial, bronchiectasis and, the endobronchial treatment of, 779; cerebral, as a complication of bronchiectasis, 861; pelvic, rectal section for, 344; retropharyngeal, in infants, 457.

Academy of Medicine (Paris), new membership in the, 78.

Accident insurance, sick insurance, and surgery, 428.

Acetonemia, periodical, periodical vomiting or, 1087.

"Acetylsalicylic acid," sale of compound wrongly labeled, using mails to defraud, 767.

Acidosis, diabetic, determination of the, by measurement of the tension of the CO_2 of the alveolar air, 520; in disease, significance of, 163, 210, 295; in infants, 653; its cause and treatment, 694.

Acne, vaccine treatment of, with special reference to the rôle of B. coli, 85.

Acridine dyes in the treatment of septic wounds, 111.

Actinomycosis, intestinal, 964.

Acute febrile entity with vomiting, somnolence, and acetone, an, 79.

Addison's disease, treatment of, 1088.

Adenoid subjects with pituitary feminism, 123.

Adrenal insufficiency in the combatants, 591; two cases of, 738.

Adrenalin, action of, on the gastrointestinal tube, 817, apothesine and, anesthesia in the removal of tonsils, 413; injections, treatment of hemorrhoids by, 696; residual, sudden death in relation to, 203.

Adrenals, changes in the, after burns, 992.

Aerophagy, 949.

Agenesia on the middle line of the throat, a case of, 81.

Agglutination of human red blood corpuscles by horse serum, the, 126.

Agriculture for invalids, 422.

Airplane ambulances, 416.

Albumin in metabolism, the necessity of, 958.

Albuminuria, orthostatic, 519.

Alcohol, injection of, for the relief of causalgia from gunshot wounds, 944.

Alimentation, duodenal (jejunal), a case of perforation of the duodenum treated successfully by, 927.

Alimentary chemistry of the boche, 288.

Alvarenga prize, the, 865.

Ambulances, airplane, 416.

American, the, is coming into his own, 823; ambulance service, the, 208; base hospital, 117; board for ophthalmic examinations, 339; camps, good health conditions in, 117; fund for French wounded, 117; jazz band arrives in France, 692; Journal of Orthopedic Surgery, 1080; medical and surgical history of the war, the, 768; Red Cross, see Red Cross, American; silent cities in France, loving care for the, 868.

Americans, Italy honors, 599.

Amputated in war, the care of the, 880.

Amputation stumps, treatment of, 164; treatment and correction of, 211; painful war scars and their pains with special reference to, 121.

Amputations, kineplastic, an address on, 79.

Anaerobes in soil-infected wounds, note on, 33.

Anaerobic organisms (other than B. tetani) in the causation of tetanus, the part played by concomitant infection with, 33.

Anaphylactic shock, serious, following the injection of milk, 258.

Anaphylaxis, the myth of, 553.

Anatomical incision for inguinal and femoral hernia, 877.

Anatomy, fetal, of the female pelvis, 657.

Anderson, H. B.; the relationship of oral sepsis to systemic disease, and its bearing on treatment, 311.

Anecdotal medicine and its neglect, 904.

Anemia of the lower limbs obtained by compression with a pad attached to a lever, 346; pernicious, complicating pregnancy, 701; pernicious, familial occurrence of, 1132; postmalarial, 459

Anemias, value of splenectomy in the treatment of some of the, 351; recognition and treatment of the, 350.

Anesthesia, intratracheal, 73; local, cesarean section under local, 962; spinal, by "barbotage," 638; spinal, in war surgery, 419.

Anesthetic in latent case of shell gas poisoning, case of sudden death after an, 780.

Anesthetics, lay, 731.

Animal extracts for treating wounds, 823.

Ankylosis, stiff knees without, following wounds of warfare and its treatment, 1000.

Anomalies, congenital, of the kidney and ureter, the clinical significance of, 87.

Anthrax from shaving brushes, 248.

Anthropometry of soldiers, 1023.

Antianaphylactic treatment of various affections, 739.

Antiformine, preparation of antigens for Wassermann's reaction with, 81.

Antirabic vaccination in Cuba, 999.

Antiscorbutic value of vegetable juices, 1125.

Antisepsis, deep, in wounds of warfare, 211; new German method of, 1074; treatment of wounds by, with bichloride of isoethylhydrocuprein, 258.

Antityphoid inoculation in the Canadian army, 433.

Aortic valves, traumatic rupture of the, 428.

Apothesine and adrenalin anesthesia in the removal of tonsils, 413.

Appendicitis, acute, complicating epidemic influenza, report of eight cases of, 919; some of the postoperative sequelæ of, 879; chronic, gastric and duodenal ulcer and, 638; from gassing, 283; in children, 602; significance in the diagnosis of, 211.

Appliances, professional judgment in the use of, 856.

Arm, Sauerbruch's artificial, 782.

Armistice celebration, psychology of the, 1127.

Army, appeal of American Reserve Corps to the members of the American Pediatric Society, 1050; base hospital No. 6, 380; camps, empyema in, treatment of, 304; health in, 552; influenza in, 770; pathology of the epidemic of streptococcal bronchopneumonia in the, 471; pneumonia in the, 173; pneumonia of the, pathology of, 38; casual detachment as tested at Camp Cody, value of, 788; chiropodists in the, 374; constipation in the, 591; demobilization of the medical officers of the, 1082; examinations, uniform physical standard to govern all, 245; foot problems and treatment with unseasoned troops, 791; health of the, 460, 859; health statistics of our fighters, 868; hookworm infection in the, 244; importance of eliminating mentally unfit, 461; laboratory in France, 860; libraries for the, 380; library is growing, 777; low death rate from disease in the, 374; malaria in the, 592; medical corps, losses in the, 78; medical museum of the surgeon-general's office, the wax-modeling department of the, and the application of the art to general medical, 663; medical prophylactic work in the, and its application to the civil population, 1095; Miss Julia Stimson made head nurse of, 1084; negro in the, 380; neuropsychiatry in the, 482; orthopedic surgery, organization of division of, in U. S. Army with expeditionary force, 789; phychological examining in the, 482; rotary microtomes desired for the, 26; school of nursing endorsed by general medical board, 20; service, cardiac conditions that disqualify for, 438; mentally deficient recruits for the, 550; special training battalion of the twenty-sixth division, 788; Surgeon-General, annual report of, 1075; tuberculosis bill well supported, 683; tuberculosis in the, 306; urinary spirochetosis in the, 944; value of nervous and mental examination in the, 349; veterinary force sufficient to meet the needs of the, 68; Y. M. C. A. educating the, 207; and navy, influenza and pneumonia in, 637; influenza in the,

509, 593; British, in India and the Far East, vegetable ration of the, 1031; maintaining the health of the, 198; medical work in the, 108; prevention of sickness in the, 373; French, three American women commissioned in the, 868; of the Isonzo, control of epidemics in the, 826; the struggle against infectious diseases in the, 1045.
Aronson, Capt. J. D., and Major S. A. Friedberg, Demonstration of diplococcus meningitides in the adenoid tissue of the nasopharynx, 1017.
Arrhythmia, "absolute," experiments in the use of quinidine in, 913.
Arsenical treatment of syphilis, 1105.
Arsenobenzol, treatment of puerperal blood stream infection by means of, 702.
Arsphenamine, problem of combating septicemia with especial reference to the use of, 921.
Arteriosclerosis, prodromal symptoms of the nervous form of, 366, 392.
Arthritis, protein treatment of, 139; septic, gunshot wounds of the knee joint with, 695; subacute and chronic, in horses and cattle, certain structural changes in, 127.
Aseptic technique in obstetrics, 879.
Asthenia, neurocirculatory, 36, 384.
Asthma, bronchial, constitutional hypersensibility and, 387, 999.
Asthmatics, the results of tests for food protein sensitiveness in a small group of, 966.
Aspinwall, F. E.: the homigrade thermometer, 281.
Aspirin habit, a case of, 767.
Astigmatism, variable hyperopic, in children and its correction, 276.
Ataxia, pseudo cerebellar, from lesions of the temporal lobes, 472.
Athens, University of, and the war, 465.
Athletes not short lived, 339.
Athletic old man, the, 201.
Atrophy of the optic discs, convenience of treating old cases of, 1043.
Atropine, curative action of, on certain manifestations of the hypertonic infant, 475.
Auricular diseases, the place of ipecacuanha in the treatment of, 356, 389; fibrillation and flutter, differentiation of, and their treatment, 398.
Autopsy service in a military hospital, 126.
Autoserotherapeutic treatment of typhus fever, successful results with, 472.
Auxohormones and other agents in the feeding of the young, a preliminary report upon the value of, 1050.
Aviation, breakdown in flying, analysis of causes of, with notes on the nervous mechanism of the flying man, 871; medical problems of, 372; recruit, the cardiovascular problem in the, 875.
Aviators, cardiac hypertrophy in, 734; essential characteristics of successful and unsuccessful, report on the, with special reference to temperament, 780; is there a disease of? 33; the physiology of, 681.
Azotemia, stages of, in Bright's disease, 472.

Dunn, B. Sherwood, the arsenical treatment of syphilis, 1105; syphilis in 1918, 933.
Duodenal contents, fractional examination of the, 172.
Duodenum, congenital stricture of the, brief report of a case of, operation, death, 1051; perforation of the, case of, treated successfully by duodenal (jejunal) alimentation, 927; radiological examination of the, by the use of a new technique of radioscopy and radiography, 81.
Dutton, W. Frost, Gingival septicopyemia, 893.
Dysentery at Dresden in the summer of 1917, epidemic of, 122; amebic, is salvarsan of value in, 34; cystic colitis and its relation to, 604; etiology of, 112; follicular, and cystic colitis, 782; Galician, 211, 258.
Dyspepsias of war, 605.
Dyspnea, diagnostic study of conditions in the throat producing, 218; painful, symptomatology of, 375.
Dystrophy adiposa genitalias in women, a study of, 704.

E

Ear conditions in young children, a survey of, 162.
Echinococcus cyst of the liver, 1007.
Eclampsia, conservative treatment of, two and one-half years' experience with the, 527; and placenta previa, is cesarean section justifiable in? 527.
Eczema, acute, due to faulty metabolism of food elements, 911.
Edema, cerebral, heat stroke with a second study of, 255; from pressure, 780; hunger, 296; chloremic, of non-nephritic origin, 564.
"Edema disease," the condition of the blood in, 826.
Edgar, Thomas W., drug addiction and the medical practitioner, 194.
Effort phlebitis, 640.
Egg shortage, the, 910.
Egypt, commission on public health in, 951.
Einhorn, Max, a case of perforation of the duodenum treated successfully by duodenal (jejunal) alimentation, 927.
Elbow and shoulder, resection of, 829.
Electromagnet, use of, for search of deep-seated bullets, 871.
Electrotherapy and hydrotherapy, 791.
Elephantiasis, Kondoléon operation for, further experiences with the, 318.
Embolism, mesenteric, and thrombosis, 462; post-operative pulmonary, due to the condition of the blood, 80.
Emetine, ipecacuanha and, in therapeutics, 718
Empyema, acute and chronic, treatment of, particularly empyemas following wounds of warfare, 696; an epidemic of streptococcus pneumonia and, at Camp Dodge, 35, 471; in the army camps, treatment of, 304; surgical treatment of, notes on the, 751; treatment of, by the Carrel-Dakin method at the war demonstration hospital, the Rockefeller Institute for Medical Research, preliminary report, 236.
Encephalitis, epidemic, 256, 957; lethargic, 1088.
Endocarditis, acute, relation of war wounds to, 173; chronic septicemic, with splenomegaly, remarks on; its treatment by splenomegaly, 175; experimental vegetative, 431; rheumatic observations on the nature and symptoms of cardiac infection in childhood, 257; scarlatinous, 958.
Endocrinology, Italian savants and, 595.
Endothelioma of the frontal bone, 829.
English College of Surgeons, 290.
Enteritis, pernicious staphylococcic phlegmonous, of the ileum, 211.
Enteroptosis, medical treatment of, 1066.
Enterostomy and enteroculostomy in the treatment of acute intestinal obstruction following pelvic operations, 518.
Entry, the point of, 191.
Enuresis, 203; etiology and treatment of, 216; war, and its relation to the elimination of chlorides and carbohydrates, 471.
Eosinophile cells in urinary sediment, a contribution to the study of membranous ureteritis, 1131.
Eosinophilia, prurigo, lymphadenia and, 1132.
Epidemics, control of, in the army of the Isonzo, 826; in 1918, movement of, 686; in Russia, 421; Paris, of the XVI century, 1076; unidentified in Argentina, 688.
Epidemiology, practical consideration of, drawn from a classification of streptococci, 39.
"Epilepsy of War," notes of the etiology of epilepsy, particularly the, 81, 122, 123.
Epileptics, expert military examination of, 564.
Epiphora, overflowing tears, and its management, 587.
Epithelioma, treatment of, 249.
Epsom college, 207.
Epstein, J., chronic obso .e fever in children, 897.
Erysipelas, propbylaxis of, with antistreptococcic serum 122; treatment of, by silver nitrate according to Gangele's technique, 81.
Esophagus, bronchi and, obscure foreign bodies in the, 477; hypertrophy, dilatation and stricture of the, case of cardiospasm followed by, treated by gastrostomy, and subsequent dilatation of the esophageal stricture, 1051; idiopathic dilatation of the, 1045.
Eugenics, war's effect on, 338.
Eunuchoids, disturbances of the internal secretions in, 33.
Exanthemata, changes arising in the cutaneous capillaries in the, 346, in paratyphoid A, 519.
Exhibition of British scientific products, 422.
Exophthalmic goiter, see *Goiter*.
Expert testimony, medical, 1072.
Exploratory puncture of the chest, hemoptysis following, 1003.
Explorers and adventurers, medical, some of our, 712
Extrasystoles, interpolated ventricular, and the theory of contraction from excitation, 386.
Eye, cellulitis of the upper lid due to a foreign body, report of a case, 1130; concussion injuries to the, 460; symptoms of recurrent fever, 739; malingering from the standpoint of the, 569; clinics, New York city curtails work of, 597; muscles, herpes zoster nasofrontalis with extensive paralysis of, 872; strain,

polliikiuria as a functional disturbance due to; causes of excessive frequency of micturition, 1085.

F

Farcy in the felidæ, 817.
Farnell, Frederick J., is there a clinical entity in acute vasomotor paralysis (preliminary communication), 984.
Fat embolus as a cause of the phenomena of post-traumatic shock, 1044; percentages, low, disadvantages of, 1094.
Fatigue and exhaustion, remarks on phenomena and energy renewals, 602.
Fats in the diet, significance of, 426.
Fear, acquired morbid, 166.
Febrile entity, acute, with vomiting, somnolence, and acetone, an, 79.
"Febrile pandemic," the, 1054.
Feebleminded delinquents seen in court, studies in personality among, 382; in Canada, care of the, 1128.
Feeblemindedness, maternal impressions and, 1113.
Feeding in marasmus, 51; breast, the establishment and maintenance of, 624.
Fees, doctors increase, 289.
Felidæ, farcy in the, 817.
Fever, blackwater, intravenous saline in, 871; chronic obscure, in children, 897; enteric, in British army, 902; hemogiobinuric bilious, 1044; pappataci, 420; ratbite, a case of, 372; recurrent, eye symptoms of, 739; scarlet, see scarlet fever; three day, 827; three day, epidemic of, in Europe, 335; typhoid, see typhoid fever; typhus, see typhus fever, with sarcoma, 473.
Fibrin as a means of defense and cure, 871.
Fibroid induration of the corpora cavernosa, 70; tumors, two hundred and ten, treated by radium, 702.
Fibroids, *x*-ray treatment of, final results, 702.
Fine, M. J., experimental test with copper and potassium cyanide in tuberculosis, 99.
Fischer, Louis, the superior longitudinal sinus in infants; its value in transfusion, and for rapid medication; its adaptability in procuring blood for diagnosis, 399; types of influenza in infants and children seen in the current epidemic, 763.
Flagg, Paluel J., lay anesthetists, 732.
Flat foot, can it be cured? 470; soldier's heart, myalgia, boot heels as a cause of, 738.
Flavine, value of, a clinical appreciation, 695.
Fleas, smallpox and, 463.
Flying, see aviation.
Focal infection, see infection.
Follicular dysentery and cystic colitis, 782.
Food conservation, public health and, in Canada, 735; control in Canada, 954; during War, the nature and effects of, 913; elements, acute eczema due to faulty metabolism of, 911; infection, epidemic of diphtheria from, 782; poor, effects of, in Austria, 1037; protein sensitiveness, the result of tests for, in a small group of asthmatics, 966; proteins in, relation of the, to the cause of disease, 145; question, the, 1128; questions, concerted action upon, 76; stringency and its consequences in Germany, 729; supply of Great Britain, 422; value, comparative, of protein, fat and alcohol in diabetes mellitus as measured by the nitrogen equilibrium, 172; war, and gastric chemisin, 1131.
Foot, common deformities and disabilities of the, 492; disabilities in the military service, 832; flat, see Flat foot; in health and disease, the, 673; of the American soldier and its care, the, 880; problems and treatment with unseasoned troops, 791; prophylaxis in the soldier, 792; weak, an analysis of the, with reference to wounds in the use of descriptive terms in teaching, 49.
Fractures, of the tibia following the removal of a bone graft, 112; treatment of, in warfare, 901; comminuted, from bullets, is radical excision of the wound proper in, 649; compound, more especially, contribution to the technique of infected wound closure, 32; compound, of metacarpals, with gas bacillus infection, amputation of hand excent thumb after, 1006; compound, of the tibia, fibula, and femur in a young child, nail fixation, 1006; intraligamentous, at the ankle (two cases), 479.
Friedberg, Major S. A., and Capt. J. D. Aronson, Demonstration of diplococcus meningitidis in the adenoid tissue of the nasopharynx, 1017.
Friedman, Lewis, purpura rheumatica, 1017.
Friedmann, antituberculous remedy of, radiological experiments with the, 782.
Front, disturbances of micturition at the, 122; management of traumatisms of the kidney in the dressing sections at the, 165.
Furunculosis and carbuncle, treatment of, 211.

G

Galenicals, clinical study of the variable therapeutic potencies of the, and their inherent unreliability, 357, 389.
Gall bladder and biliary ducts, surgery of the, 162; disease and its differential diagnosis, 962; typhoid infection of the, pathogenesis of, 418.
Gallstones, prevention of the recurrence of symptoms following operation for, 962; disease, the modern treatment of, as affected and controlled by duodenal intubation, 575.
Gangrene, gas, see *Gas Gangrene;* juvenile peripheral, in infectious diseases (1), diphtheria, 620; tetanus and gas, treatment of, 858.
Gangele's technique, treatment of erysipelas by silver nitrate according to, 81.
Gas gangrene, cure claimed for, 153; of war wounds, researches into, 212; serotherapy of, 550; tetanus and, treatment of, 858.
Gas poisoning, observations on, 942; irritant, treatment of, 781; shell, case of sudden death after an anesthetic in a latent case of, 780.
Gassed cases, report on a series of, 724.
Gassing, iodine in the treatment of, 725.
Gastric chemisin, war food and, 1131; origin, narcolepsy of, 993; secretion in wartime, 1087; sensitiveness in cold, 1044; ulcer, see *Ulcer.*
Gastrocolonopexy operation, Goffe's, description of, 703.
Gastrointestinal headaches, 454; tube, action of adrenalin on the, 817.
Gastroptosis, a painful spot in, 81.
Gauze mask in the prophylaxis of contagious diseases, the, 387.

Icterus, hemolytic, two operative cases of, 521; clinical and experimental researches on, 1087; nonsprochetic epidemic, 1121.
Idiocy, amaurotic family, energy metabolism in an infant with, 1093.
Ileocecal valve incompetency, radiographic diagnosis of, 879.
Ileum, pernicious staphylococcic phlegmonous enteritis of the, 211.
Ileus by torsion, case of, 605.
Immobilization, curse of, 1130.
Immunity and tissue transplantation, 12; reactions in hydrated and concentrated tissues, 194.
Immunization, active, with vaccine virus against influenza, value of, 919; in hay fever, present status of, 470; of the infant against diphtheria, 615.
Immunized skin flaps, the cure of cutaneous ulcers and bone fistulæ following wounds from missiles by, 33.
Immunizing properties of bacterial vaccines, prepared after various methods, a study of the, 85.
Indian medical service, changes in the, 467.
Industrial heat hazards, 23; workers, want medical examinations for, 421.
Infants, acidosis in, 653; and children, types of influenza in, seen in the current epidemic, 763; and maternal welfare in rural communities, problems of, 1137; breast-fed, death from tuberculous meningitis in a, at ten weeks of age, 1053; energy metabolism of an, with amaurotic family idiocy, 1093; home care of the, 1136; hypertonic, the curtive action of atrophine on certain of its manifestations, 479; life, the obstetrician's responsibility for the conservation of, 701; mortality, prevention of, city nurse as an agent for the, 1137; mortality rate in Germany, 420; mortality rate of New York lower, 338; mortality, syphilis and its relation to, 1130; mortality, work of the training school of the Philadelphia General hospital in preventing, 1137; preliminary report upon the value of auxohormones and other agents in the feeding of, 1050; results of preventive vaccination of, against tuberculosis, 1131; retro pharyngeal abscess in, 457; variations in the lipoid (fat) content of the blood of, under certain nutritional conditions, 1047; welfare in Canada and other countries, rural work for, 1137; young, a case of "cerebral" in a dilated stomach; spasm of diaphragm, 1052.
Infantile mortality and tuberculosis in the province of Quebec, 381; paralysis controversy, the, 247.
Infantilism and other hypoplastic conditions of the uterus, 694; pancreatic, case of socalled, 285; with report of two cases illustrating the Brissaud and Frölich types respectively, 1004.
Infections, catarrhal, of the respiratory tract, prophylactic vaccinations against, 870; focal, diseased tonsils and, 870; mouth, vaccine dosage in the elimination of the systemic effects of, 17; multiple, a study of the relation of one infection to another, 998.
Infectious diseases at Belgrade in 1916, 81; diagnostic significance of the leucocyte blood count in, 959; in the army of the Isonzo, the struggle against, 1045; the leucocytic formula as a diagnostic means in, 1000.
Influenza, 510; aborting the grippe, 820, 908; abortive treatment of, with quinine dihydrochloride, 1081; alkaline treatment of, 908; among German reserves, 246; and its complicating pneumonias, an effective treatment of lobar and bronchial pneumonia, also of, 720; and pneumonia in army and navy, 637; and purulent bronchitis, 603; bacteriological and serological examination of, some new procedures in, 649; becomes more widespread, 640; cases, autopsy finds in, 1068; cinnamon oil in, 176; clinical, etiological and epidemiological observations on the so-called "Spanish disease," 782; committee to study, 1080; commission, work of, 1079; deaths in camp, 1075; decreases in camps, 1119; disappearing from army and navy, 813; discussion of epidemic, New York Academy of Medicine, 783; discussion on, at the Academy of Medicine, Paris, 953; epidemic, the, 910, 1039, 1082; epidemic, acute appendicitis complicating, report of eight cases, 919; epidemic, clinical features of the recent, 1103; epidemic in Europe, 724; epidemic in New York city, present status of the, 1090; epidemic on the wane, 773; epidemic of (in England), 252; epidemic, physical findings in pneumonia complicating, 919; etiology of the, 826; "febrile pandemic," the, 1034; in army camps, 770; in army and navy, 509, 593; in Canada, 955; increased effort to arrest grippe, 1127; incubation period of, 999; in Eastern Canada, 783; in Germany, 422; in London, 866, 951; in Montreal, 381; in other countries, 730, 773; in Paris, 560; 997, 1084; in Porto Rico, 1080; limit surgical operations during the epidemic, 774; microbial flora of the grippe, 905; mortality exceeded that of war, 906; Naples swept by epidemic, 597; New York's record, 906; New York State Commission to study, 774; observations on a small localized epidemic of, with special reference to the incubation period, 999; on parotitis as a complication of, 1117; on the wane, 819; pandemic, the, 686, 914, 990, 1037; pandemic, and the war, 903; pandemic, diagnosis in the, 949; patients, after-care of, 865; pneumonia in 1847, 1122; precautions, 690; prophecy and, 995; prophylactic vaccines in, 820; quinine in the prevention of, 1036; reaches Alaska, 906; report of the commission appointed by the Paris academy of medicine upon the epidemic of grippe, 1038; reviving, 1078; salicylates in the treatment of, values of, 856; situation, the, 596; "Spanish," 113, 515; Spanish, a prophylactic vaccine against the socalled, 979; Spanish grip again before the academy, 911; Spanish, arrives in New York, 838; Spanish, origin of the socalled, 632; still on the increase, 730; Surgeon-General Blue issues bulletin on, 512; types of, in infants and children seen in the current epidemic, 763; value of active immunization with vaccine virus against, 919; vernal, bacteriology of, 555; Warburg's tincture in the treatment of, 948; world plague, 1123.
Influenzal type, on a disease of, 519.
Injuries at birth, their effect upon the child and their prevention, 523; back, and their relation to the workmen's compensation law, 1085; gunshot, chronic osteomyelitis due to treatment of, 48; labor, recognition and management of, 963.
Inoculation, antidysentery, 20.
Insane, nurses needed for the, 466.
Insanitation, urban, 821.
Insanity defense, questions to medical expert, 458; in Peru, 685; military service and, 635.
Instinct, emotion, and personality in disorders of the heart, the rôle of, with suggestions for a clinical record, 956.
Insurance, life, association of, presidents, 1037; life and health, American Red Cross, 469; sick, accident insurance, and surgery, 428.
Internal secretions and faulty metabolism, relation of, to mental perversions, 4; disturbances of, in eunuchoids, 33.
Internist, general diagnostic study by the, 602, 646.
Intestinal parasites in children, 215, 426.
Intestinal obstruction, acute, 274; acute, following pelvic operations, enterostomy and enterocolostomy in the treatment of, 518; chronic, two cases simulating diverticulitis of the sigmoid with, 829.
Intestinal stasis, treatment of, by duodenal lavage, 268, 300; ptosis, surgical treatment of, 1091.
Intestinal oxalic lithiasis, 727.
Intestine, accidental removal of, through the vaginal vault, 963; rectosigmoid, physiology of the, 465
Intratracheal anesthesia, 73.
Inthrathecal injections of horse serum in the treatment of chorea, 1095.
Intravenous injection, death under, 1038.
Intubation, duodenal, the modern treatment of gallstone disease as affected and controlled by, 575.
Intussusception, case of, 1052.
Invalids, rationing of in England, 340.
Iodine in the treatment of gassing, 725; why? what iodine? 546; fumes in the treatment of ulcers, 130.
Ipecuanha and emetine in therapeutics, 718; In the treatment of auricular diseases, the place of, 356, 389.
Iridocyclitis, epidemic parotitis with, three cases of, 123.
"Irritable heart of soldiers," sympathetic nervous system and the, 295.
Ischemic myositis, see Myositis.
Isotonic saline solutions, study of globular resistance in various, 123.
Italian savants and endocrinology, 595.

Periosteum, rôle of the, in the formation of bone, 123.
Peripheral nerves, pathology of the, in gunshot wounds, 790.
Peritoneal cavity, use of Dakin's solution in suppurative conditions within the, 704.
Peritonitis, tuberculous, 479; do not sterilize women when operating for, 964.
Perversions, mental, relation of internal secretions and faulty metabolism to, 4.
Pharmacists, naval, correspondence school for, 333.
Phenolphthalein as a test for renal function on, 915.
Phillips, W. F. R., patent foramen ovale and its relation to certain cardiac murmurs, 402, 432.
Phlebitis effort, 640.
Phthisiophobia and phthisiomania in France, 554.
Physical condition, is it worth while for the man of fifty to get into, conservation of man power at or beyond full maturity? 517.
Physicians, appeal to, in behalf of the fourth Liberty loan, 529; German, concerning fellowship with, 1034; training of, for public health service, a plan suggested, 319.
Physiology of swimming, 1078; of the rectosigmoid intestine, 465.
Pituitary extract in obstetrics, 377; use and abuse of, 694; feminism, adenoid subjects with, 123.
Plagues, contagious, protective mask in, 1077.
Plastic operation, "muff," the repair of large loss of soft tissue by a, 605; on the face for an exceptionally extensive loss of tissue, 122.
Platinum, conservation of, through physicians and dentists of the country, 557; scrap, no longer needed, 909.
Plea for a more systematized study of a patient's life needs, the bread life, 583.
Pleurisy, clinical observations on, 520.
Plimmer, Professor H. G., death of, 159.
Pneumatosis, gastric, 510.
Pneumococcemias in children, 915; prolonged, 915.
Pneumonia, 920; acute lobar, relationship of the leucocyte count and bone marrow changes in, 127; at a base hospital, 471; central, 1131; clinical study of eight hundred cases of, 38; complicating influenza, physical findings in, 919; influenza and, in army and navy, 637; influenza, in 1847, 1122; in the army camps, 173; insufflation of oxygen in, 689; lobar, serum treatment of, 174; lobar and bronchial, an effective treatment of, also of influenza and its complicating pneumonias, 720; of the army camp, pathology of, 38; prevention of, 426; serum and vaccine treatment of the, 270; serum treatment of, 304; some recent results of coordination of laboratory and clinical researches in, 921; sputum, rapid method for the determination of the type of pneumococcus in, 613; streptococcus, 38; streptococcus and empyema at Camp Dodge, epidemic of, 38, 471; symposium on: unique findings gathered from the observation of eleven hundred cases of pneumonia in a base hospital, 37; the "endless chain" treatment of, 903.
Pneumothorax, artificial, five years' experience with, 434; operative detachment of pleural adhesions in order to produce an, 605; the treatment of chest wounds by, 1055; spontaneous, in non-tuberculous subjects, on, 386.
Poisoning from hexamethylene tetramine, 650; gas: see Gas poisoning; myrtol and eucalyptol, 171; T. N. T. experimental, 125; prevention of, 152.
Poliomyelitis, intrauterine, 88; specific prevention of, 613.
Pollakiuria as a functional disturbance due to eyestrain; causes of excessive frequency of micturition, 1085.
Polyuria, essential, Insipid diabetes or so-called, 863.
Porter, William Henry, unique case of rheumatism and its management, 627.
Postures, faulty, perils from, 540.
Pregnancy, chemical examination of the blood and urine in normal pregnancy and in the toxemia of, some observations of the, 526; extending the care of, 563; extrauterine, tubal and ovarian hemorrhage, its etiological relation to pelvic hematocele and, 699; goiter in 563; pernicious anemia complicating, 701; pernicious vomiting in, parotitis following induced abortion in a case of, 647; toxemia, a study of various cases of, 963; triplet, cancer of the cervix complicating, 703.
Pregnant munition worker, the, 558; women, employment of, in munitions factories, thoughts on the, 603; woman, the heart of a, 963; working woman, 861.
Premature child, care of, in the home, 524.
Prematurity, treatment of, 214, 695.
Prenatal care, importance of, 1136; value to both mother and child of, 523.
Preoperative purge, the, 512; treatment, rational, with special reference to purgation, 210.
Prognosis of chronic diseases an undeveloped opportunity for the study of, 678.
Prohibition, the medical profession of Ontario and, 735.
Prolapsus uteri, 700.
Prophecy and influenza, 995.
Prophylactic work, medical, in the army and its application to the civil population, 1095.
Prophylaxis of contagious diseases, the gauze mask in the, 387.
Prostate gland, hypertrophy of the, observations on, 1027; question, the, 607.
Prostatectomy, anatomical results after, 610; perineal, 569, 610.
Prostatics, renal function in, 473.
Protein bodies, the therapeutics of, 826; in food, the relation of the to the cause of disease, 145; sensitiveness, food, the results of tests for in a small group of asthmatics, 966.
Prurigo, lymphadenia, and eosinophilia, 1132.
Pseudoleucemia, acute, case of, 827.
Psoriasis, radium in the treatment of, some experiences with, 765.
Psychiatry, advanced, application of the principles of, 966.
Psychic disturbances in locomotor ataxia, 69; element as an important factor in the development and treatment of peptic ulcer, 324.
Psychoanalysis, resistance and transference in, 542.
Psychological examining in the army, 482.
Psychology of mental confusion, 283; of peace, the, 1038.
Psychoneuroses of the war, the, 881; war, and complementary phenomena, biological factors of the, 794.
Psyches and psychoneuroses, surgery in its relation to the, 315, 351; effect of the selective draft law in the production of, 806; manic-depressive, and the manic-depressive constitution or temperament, the milder forms of, 969.
Public health and political progress, 467, 514; and food conservation in Canada, 735; commission of, in Egypt, 951; contract declared illegal because of danger to, 414; in Cuba, 950; service, programme for the nationwide control of, 1134; service, training of physicians for, a plan suggested, 319; service urges care in reporting communicable diseases, 158.
Puerperal blood stream infection, treatment of, by means of arsenobenzol, with report of cases, 702.
Pulmonary fat embolism and its relation to traumatic shock, 825.
Pupillary changes, clinical value of, 254.
Purgation, rational preoperative treatment with special reference to, 210.
Purpura abdominalis in early life, 215; rheumatica, 1029.
Pylorospasm, case of, 959.
Pyonephrosis, unilateral, following a bullet wound of the bladder, 81.
Pyorrhea alveolaris, 589.

Q

Quantitative analysis of the mercury eliminated in the urine, the relative efficiency of the different mercurial preparations in the treatment of congenital syphilis in infants and children as determined by a, 1047.
Quinic alkaloids and their derivatives, dislnfection with, 519.
Quinidine, experiments in the use of, in "absolute" arrhythmia, 913.
Quinine alkaloids and their chemical alkaloids and their chemical substitutes, treatment of malaria by, 872, 914; as a cardiac medicament, 296; dihydrochloride, abortive treatment of influenza with, 1081; in the prevention of influenza, 1036; observations on the resistance of hematozoa to, 386.

R

Rabelais' mention of parts of the human skeleton, 279; references to hair by, 982.
Rabies in England, 690; recrudescence of, as a result of the war, 1078.
Radiculitis, is migraine a? 24.
Radiographic diagnosis of ileocecal valve incompetency, 879.
Radiological diagnosis of gastric and duodenal ulcer, 122; experiments with the anti-tuberculous remedy of Friedmann, 782.
Radiology of gastric and duodenal ulcers, the, 346.
Radioscopy and radiography, radiological examination of the duodenum by the use of a new technique of, 81; of the stomach after normal repast, 564.
Radium and heat, the use of, in the treatment of cancer of the jaws and cheeks, 824; influence of, on cancer tissue, 741; internal use of, 586; in the treatment of psoriasis, some experiences with, 765; on cataract, action of, 120; some observations and results in the treatment of four hundred cases with, 617; technical problems connected with the use of, by the gynecologist, consideration of some, 703; therapy in hyperthyroidism, 596; some of the fundamental scientific principles of, 741; treatment, course of myelocytic leucemia as influenced by splenectomy following, 168; of cancerous mucous membranes, by, 741; for myelocytic leucemia, splenectomy following, 1020; two hundred and ten fibroid tumors treated by, 702; uterine cancer treated with lantern slide demonstration of, 741; *x*-ray and, notes on, 437.
Railway spine, effect of the verdict on, 903.
Rammstedt method, twenty-six cases of pyloric stenosis in private practice, with operation by the, 1048.
Rankin, Egbert Guernsey, observations on gas poisoning, 942.
Rapplaye, W. C. an undeveloped opportunity for the study of the prognosis of chronic diseases, 678.
Rats, destruction of, in ships, 866.
Raynaud's disease, mitral stenosis and, 1045.
Reasoner, Lt. Col. M. A., Rotary microtomes desired for the army, 26.
Reconstruction, see Rehabilitation.
Recruiting, medical side of, 115.
Rectocolonic affections and operations, including (a) colotomy for multiple adenomata (polyposis), (b) resection of the ileocecal angle for neoplastic tuberculosis, (c) vaginal excision of the rectum for carcinoma, and (d) the technique of anorectal operations performed under local anesthesia, 1009.
Red Cross, American, and the French schools, the, 73; civil work for March, 253; enormous growth of, 814; establishes new activity, 859; everywhere, 30; foreign branches of, 637; health unit for Italy, 417; hospital at Liverpool, 732; hospitals, new, 246; in England, 642; in Italy, 469; June report of the, 599; life and health insurance, 469; national testimonial at Sorbonne to, 1034; new headquarters in Paris, 868; obliged to flee from Germans, 515; Paris ambulance section, excellent work of, 560; refugees succored by the, 161; relief work in Italy, 292; reorganized in France, 813; starts ambulance service, 417; to care for captives, 460; what she is doing for the French children, and its application at home, 1096; women, French general praises, 777; work in Italy, 417; work in near East, 726; in Palestine, 1032; work of, for civilian France, 637; work, statistical report of, 342; work will go on, 859; mission, Japanese, arrival in Paris, 692.
Redfield, Casper L., testing facts and theories of heredity, 105.
Reeducation in the functional disabilities of actual war service, 790; of the blind soldier, 332; of the injured soldier, 875; regeneration of joints, on, 649, 696; of striated muscle, the, 872; of tissues in man, 826.
Rehabilitation bill, President Wilson signs, 21; of disabled American soldiers abroad, 284; of disabled soldiers in general military hospitals, 284; of disabled soldiers and sailors, social responsibility in the, 705; of disabled soldiers, blinded soldiers as masseurs in hospitals and

sanatoria for reconstruction and, 709; of the disabled soldier in Canada, 857; soldiers' civil reestablishment hospital (Canada), 1128.
Relapse in hysterical manifestations, prevention of, 913.
Renal affections, chronic, the nature and treatment of, 81; affections, elimination of coloring matter by the urine in certain, 296; examination, normal and pathological, 297; function in prostatics, 473; function, on phenolphthalein as a test for, 915; lithiasis in a urological center for troops, 1001.
Reproduction, adequate, 1137.
Research, medical society establishes fund for, 205; original, for the young physician, 862; scientific and industrial, in Canada, 1128.
Resection of elbow and shoulder, 829.
Respiration, therapeutics of, 642.
Rest after meals, the importance of, 241.
Resuscitation, a new technique of heart massage, with a case of, 957; commission, third, 1139; recommendations, 1140; resolutions, 1140.
Reynolds, Walter S., a consideration of some of the problems of hereditary syphilis, 142.
Rheumatic conditions, intramuscular injections of colloidal sulphur in the treatment of, 765; conditions, relating to factors that may cause, 411; or indurative headache, 163.
Rheumatism, unique case of, and its management, 627.
Rhythmical breathing, 433.
Rice, James Francis, medical treatment of exophthalmic goiter, 97.
Rickets, causation of, 1120; in relation to housing, 288.
Rickettsia bodies in lice, association of, with trench fever preliminary note on, 737.
Righthandedness in its relation to visual conditions, 383.
Robbins, F., juvenile peripheral gangrene in infectious diseases, (1), diphtheria, 620.
Robinson, Beverley, a word about the drug treatment of nervous exhaustion, 410; how to treat a cold simply and effectively, 558; influenza precautions, 690; the value of salicylates in the treatment of influenza, 856.
Roentgenological service, military, development of, in New York City, 66.
Roentgen ray, diagnosis and treatment of tuberculosis with the, 839; diagnosis, clinical aspects of peptic ulcer with special reference to, 171.
Round, John, cancer, a disease of deficiency, 184.
Royal air force medical service, 732; army medical corps, the gallantry of the, 252.
Rugh, J. Torrance, a new operation for hallux valgus, 793.

S

Saccharin as a food in diabetes, value of, 1071.
Sacrococcygeal region, principles underlying the surgical treatment of certain infections about the, 980.
St. Katherine's Lodge in Hyde Park, London, a brief description of the work at, 788.
Salicylates in the treatment of influenza, value of, 856.
Saliva as a vulnerary, 113.
Salvarsan, is, of value in amebic dysentery, 34; the so-called disasters from, 1045.
Sanitation and medical geography in Porto Rico, 1077.
Sarcoma, fever with, 473; of the left ovary in a child twenty-three months old, 963; hemorrhagic degeneration of myomas and their relation to, 647.
Satterlee, G. Reese, the treatment of duodenal ulcer, 265.
Sauerbruch's artificial arm, 782; method, a new method of forming a cutaneous sulcus in the preparation of stumps in, 958.
Saunders, M. B., pyorrhea alveolaris, 589.
Scaphoid scapula, the frequency and significance of, 1044.
Scarlet fever, bronchopneumonia complicating, 684; case of erosion of blood vessels in the course of, 1051; measles and chemistry of, 1043.
Scarlatinous endocarditis, 958.
Scheffel, Carl, etiology of fifty cases of drug addictions, 853.
Scheppegrell, William, hay fever pollen extracts and their standardization, 141.
Schick test for diphtheria susceptibility, result of, on five hundred selected cases, 498.
Schiller, A. Noah, retropharyngeal abscess in infants, 457.
School lunches, the value of, 378.
Schurman, Dr., of Cornell, dinner to, in Paris, 692.
Scorbutus, quinine anaphylaxis and malaria, 427.
Scurvy, antiscorbutic value of vegetable juices, 1125; antiscorbutics and intravenous therapy for, 174; infantile, focal degeneration of the lumbar cord in a case of, 126; of guinea pigs and infants, intestinal flora in, 126; report on, 1082.
Seborrheic eruptions, observations on the etiology and treatment of, a preliminary report, 604.
Secor, William Lee, an improved operation for internal hemorrhoids, 370; intramuscular injections of colloidal sulphur in the treatment of rheumatic conditions, 765.
Selective draft law, effect of, in the production of psychoses, 806.
Semilunar plica, the: a prodromal symptom of measles, 122.
Sensation, case of absence of all, 912.
Sensory changes in the diagnosis of trench fever, address (part of) on, 824.
Septic sores and nile boils, a routine treatment for, 1086.
Septicemia during the evolution of war wounds, 769; fatal, of buccodental origin, 864; problem of combating, with special reference to the use of arsphenamine, 921.
Septicopyemia, gingival, 893.
Sera, see Serum.
Sergent's white line in soldiers, 554.
Serotherapy of gas gangrene, 550.
Serum and allied materia medica in war time, 303; and vaccine treatment of the pneumonias, 270; antimeningococcus, essential properties of a potent, 169; antistreptococcic, prophylaxis of erysipelas with, 122; highly ovariolytic blood, case of "pseudovariolism" with, 165; horse, agglutination of human red blood corpuscles by, 126; horse, intrathecal injections of, in the treatment of chorea, 1095; intraspinal arsoarsphenamized, treatment of cerebrospinal syphilis, observations of the, 966; prophylactic and curative for Weil's disease, 872; therapy, intraspinal autosalvarsanized, of cerebrospinal syphilis, observations on the, 84; treatment, intravenous, of cerebrospinal meningitis, 169; treatment of epidemic cerebrospinal meningitis, 967; treatment of lobar pneumonia, 174; treatment of meningitis, 168; treatment of pneumonia, 304.
Servoss, George L., The action of chlorine on suture material, 634.
Sewage disposal problem of New York City, 502.
Sex, error of, case of, 959.
Sexton, L., observations on hypertrophy of the prostate gland, 1037.
Shamon, James W., Cancer, its causation and prevention, 530.
Shattuck lecture, the, shell shock and after, the Massachusetts Medical Society, 209.
Shell explosions, effects of, 249; gas poisoning, case of sudden death after an anesthetic in a latent case of, 780; shock and after, the Massachusetts Medical Society, the Shattuck lecture, 209; shock and other war neuroses, 91; shock, hospital for, 333; shock, war strain and, 655.
Shock and blood pressure, 769; interpretation of manifestations of, 874; period of latency of, 1031; serious anaphylactic, following the injection of milk, 258; shell, see shell shock; surgical, in face mutilations and coincident injuries, 874; traumatic, fat embolus as a cause of the phenomena of past, 1044; traumatic, pulmonary fat embolism and its relation to, 825; war, physical basis of, a plea for the more physical concept and basis of treatment of the mental and incapacitic delinquency of victims of near hysteria and shock, 224; wound and the vasomotor center, 425.
Shoulder, elbow and, resection of, 829.
Shufeldt, R. W., the wax modeling department of the army medical museum of the surgeon-general's office, and the application of the art to general medicine, 663.
Shuttle-kissing, 690.
Sickness, relation of income to, 1120.

Tonsils, diseased, and focal infection, 870; operations, 155; removal of, apothesine and adrenalin anesthesia in the, 413.

Toronto, Academy of Medicine, inauguration of a new section at the, 1128.

Toxemia, pregnancy, a study of various cases of, 963.

Toxicity, blood pressure and an experimental study of, further contributions to the treatment with digitalis preparations, 13; of eggs, 993.

Tracheotomy without loss of blood, a method of, 877.

Traditions, Semitic, death and its, 7.

Transfusion, blood, apparatus, a new, 832; at Australian dressing stations, 460; deaths following, 165; in France, 156; is homo-specific blood dangerous? 346; of blood by the citrate method, a note on the, 64; of blood in war surgery; some indications and results, and description of new modified direct method, 825; value of the superior longitudinal sinus in infants in, and for rapid medication; its adaptability in procuring blood for diagnosis, 399; "Transvestitism" with highly ovariolytic blood serum, case of, 165.

Tremor following wounds inflicted in the Russo-Japanese war, 88.

Trench fever, 173; a recent account of, 991; association of Rickettsia bodies in lice with, preliminary note, 737; infection, 28; sensory changes in the diagnosis of, part of address on, 824.

Trench lung, 283.

Trench nephritis, early stages of, 724.

Trinitrotoluene poisoning, experimental, 125; prevention of, 152.

Trudeau, Dr., memorial to the late, 289.

Tuberculides, Wassermann reaction in, 1132.
Tuberculosis, action of sugar on the sputum in, 336; among cattle, government begins fight on, 730; and antityphoid vaccination, 159; and many infectious diseases, the real value of fresh air in, 737; "bacillary impregnation," 511; care of the tuberculous soldier, 76; complement fixation in, technique, 614; complement fixation reaction for; clinical results, 614; conferences on, as a war problem, 421; diagnosis and treatment with the roentgen ray, 839; dispensaries, more cities to have, 72; do not sterilize women when operating for tuberculous peritonitis, 964; experimental test with copper and potassium in, 99; fighting, 30; from the standpoint of the genitourinary surgeon, 439; from the standpoint of the orthopedic surgeon, 439; glandular tuberculous conjunctivitis treated by instillations of tuberculin, 435; hospitals, county, start work on, 71; in France, 635; in Great Britain, management of, 222; in infancy, complement fixation test for, 1048; in the army, 306; infantile mortality and, in the Province of Quebec, 381; mainly osseous and glandular, fifty cases of, treated with tuberculin contrasted with fifty cases treated without tuberculin, 407, 435; more deadly than bullets, 157; North Atlantic conference, 597; occupation for tuberculous patients, 899; of the breast, 829; of the peritoneum, 439; of the stomach, with report of a case of multiple miliary tubercles, 393; on spontaneous pneumothorax in non-tuberculous subjects, 386; Papworth hall colony for the tuberculous, 599; prevention, diagnosis, treatment, and cure of, 754; presence of virulent tubercle bacilli in the blood after the exhibition of tuberculin, in cutaneous and other, 34; providing for the tuberculous at Paris, 117; pulmonary and laryngeal, experiments with a new and most efficient remedy for, 1061; pulmonary comparative results obtained in the treatment of, 436; pulmonary hemorrhage, treatment of, by the sitting position, 386; pulmonary, in the military service, 682; pulmonary, initial, stenosis and, relations between, 258; pulmonary, operative treatment for, 387; pulmonary, pathology of the cardiac liver in, 22; pulmonary, physical examination in the diagnosis of early, 922; radiological experiments with the antituberculous remedy of Friedmann, 872; report of a case of pancreatic cyst in association with tuberculous kidney and intestinal complications, 963; results of preventive vaccination of infants against, 1131; soldier and, 47 439; study of the complement fixation reaction to, 83; surgical renal, prognosis of, 87; treatment of, open windows in the, 915; treatment of so-called surgical, in special establishments and hospitals, 695.
Tuberculous meningitis in a breastfed infant, death from, at ten weeks of age, 1053; patients, former, follow-up system of the Pennsylvania department of health for, 876; peritonitis, 479; soldiers, what shall be done with the, 439.
Tumor, bladder, operative treatment of, 1055; of the brain, 88; report of a case in which the patient survived the removal of a, for thirty years, 305; surgical treatment of, a new principle in the, 563; fibroid, two hundred and ten, treated by radium, 702; malignant, of the female breast, lactation and, 212; retronasal, 856; uterine, 744.
Turpentine injections, effect of, on suppuration and inflammation, 782 infections of, in some cutaneous affections, 958; oil of, treatment of cutaneous affections by injections of, 958.
Typhoid affections, continued elimination of bacilli following, 427; carriers, treatment of, with mercurial cystin, 165; fever in New York, the morbidity and mortality of, 422; fever, intestinal perforation in, prognosis of cases of, without operation, 967; fever, should antityphoid vaccination be done during an epidemic of? 471; fever, some diagnostic aspects of, 594; infection of the gall-bladder, pathogenesis of, 418; lesions of the circulatory system, 1035; Widal's reaction, can it be employed in subjects vaccinated against, 1000.
Typhus fever, 915; autoseroterapeutic treatment of, successful results with, 470; clinical aspects of, 739; essays in prophylactic vaccination for, 80; in Paris, 24; serology of, 346; Weil-Felix bacillus immunity reaction and its pathogenic significance in, 258; Weil-Felix reaction in, nature of, 519; infection, experimental, 296; patients, are there any other bacteria besides the proteus of the Weil-Felix type which can be agglutinated by the blood of? 80.
Tweddell, F., Experiments with a new and most efficient remedy for pulmonary and laryngeal tuberculosis, 1061.
Twinch, Sidney A. and Richard Cole Newton, Fifty cases of tuberculosis, mainly osseous and glandular treated with tuberculin contrasted with fifty cases treated without tuberculin, 407, 435.

U

Ulcer, duodenal, absence of clinical symptoms during the preperforative stage of, 878; duodenal, ambulatory treatment of, 300; duodenal, operative measures in, 300; duodenal, treatment of, 265; gastric and duodenal, and chronic appendicitis, 638; gastric and duodenal, genesis of, 696; gastric and duodenal, radiological diagnosis of, 122; gastric and duodenal, radiology of, 346; iodine fumes in the treatment of, 130; leg, burns and symposium on modern treatment of, including treatment of, 130; of the bladder, elusive; further notes on a rare type of bladder ulcer, with a report of 25 cases, 698; peptic, clinical aspects of, with special reference to roentgen-ray diagnosis, 171; peptic, healing of, 171; peptic, psychic element as an important factor in the development and treatment of, 324; perforating, of the hard palate resembling tertiary syphilis, but due to a fusospirillary invasion (so-called Vincent's angina), 518; traumatic gastric, 123.
Unconscious persons, a simple procedure for preventing swallowing the tongue in, 427.
Ureter, clinical significance of congenital anomalies of the kidney and, 87; liver and bladder, surgery of the, 609; treatment of wounds of the, during laparotomy, 563.
Ureteritis, membranous, contribution to the study of, eosinophile cells in urinary sediment, 1131.
Urethra, inflammatory or traumatic strictures of the, in soldiers, management of, 165.
Urethral calculus, 165; fistulas, operative treatment of and hypospadias from bullets, 826; stricture, impassable, new operative procedure in, without perineal section 611.
Urinary tract, ascending infection of the, 1094.
Urine, elimination of coloring matter by the, in certain renal affections, 296; study of the, in criminology, 1121.
Urological center for troops, renal lithiasis in a, 1001; third reunion of the chiefs of the, 1001.
Urticaria, psychogenic, 739.
Uteri, prolapsus, 700.
Uterine disease, some observations on the nature of cancer with special reference to, 895; inertia a torn cervix versus, 239; inertia, summary of a series of cases, 563; tumors, 744; veins, escape of foreign material from the uterine cavity into the, 657.
Uterus, infantilism and other hypoplastic conditions of the, 694; prolapse of the, a vaginal hysterectomy for the cure of, when the removal of the uterus is necessitated, with special reference to the lanping of the vaginal fascia in all forms of vaginal prolapse, 700; some observations on the blood supply of the, with special reference to the operation of vaginal hysterectomy, 103; the underdeveloped, 565.

V

Vaccinated heifers, variolization of, 864.
Vaccination, antirabic, in Cuba, 999; antityphoid, should it be done during an epidemic of typhoid fever? 471; antityphus, experiments with, 472; of pupils, powers of State Board of health as to, 812; preventive, of cholera, 296; preventive, of infants against tuberculosis, results of, 1131; prophylactic, for typhus fever, assays in, 80; prophylactic, against catarrhal infections of the respiratory tract, 870.
Vaccines, bacterial, study of the immunizing properties of, prepared after various methods, 85; dosage, 84; dosage in the elimination of the systemic effects of mouth infection, 17; pertussis, further use of, controlled by the complement fixation test, 216; prophylactic, in influenza, 820; treatment of acne, with special reference to the rôle of *B. coli*, 85; virus, value of active immunization with, against influenza, 919.
Vaginal douche, the 71; hysterectomy, hemorrhage in, control of, 501; hysterectomy, some observations on the blood supply of the, with special reference to the operation of, 103; hysterectomy technique for the cure of prolapse of the uterus when the removal of the uterus is necessitated, with special reference to lapping of the vaginal fascia in all forms of vaginal prolapse, 700.
Varicella, protective therapy for, and a consideration of its pathogenesis, 1094.
Variolization of vaccinated heifers, 864.
Vascular, joint, muscle, and skin disturbances, a case with, 1053.
Vasomotor center, wound shock and the, 425.
Vater's ampulla, neoplasms of, symptomatology of, 947.
Vegetable milk, preliminary report on the use of, 1054.
Venereal clinics in Great Britain, 352; disease, bureau of, 1079; disease, compulsory examination of women for evidences of, 467; disease, control of, 338; disease control, problem of, 348; disease, demobilization and the spread of, 1125; disease in Canada, 954; disease in troops, statistics of, 459; disease, military aspect of, 416; disease, prescriptions for, 27; disease, prophylaxis of, 88; public health service program for the nation-wide control of, 1134; disease regulations in New York State, 641; disease, State and federal cooperation in the control of, 1056; disease, the most effective methods of preventing, 700; problem in the U. S. Army in the present crisis, handling of, 647.
Venous pulse, the, 427; wave in man, the rapidity of propagation of the, 771.
Ventricle, left, removal of foreign body from the, 734.
Verbrycke, J. Russell, Jr., Gastrointestinal headaches, 454.
Vertigo of the menopause, 963.
Vestibular tests, war deafness, with special reference to the value of, 345.
Veterinary medicine, federal effort to promote the science of, 237.
Vincent's angina, 387; so-called, perforating ulcer of the hard palate resembling tertiary syphilis, but due to a fusospirillary invasion 518.
Viscera, transposition of, 1054.
Visceral exsections and resections, is it good practice for the surgeon to perform, while the viscera are inflamed? 656.
Visceroptosis, a new operation for its relief, 694.
Visual acuity, impaired, in relation to indemnity, 415; conditions, right-handedness in its relation to, 383.
Vital statistics in Canada, organization of, 1128.
Vitropression, sign of, 649.
Vocational education, conference on, 24
Volunteer medical service, see Medical Service; service corps, New York committee of, 551.
Volunteer's reasons, a, 340.
Volvulus caused by round worms, death from, 65.
Vomiting, periodical, or periodical acetonuria, 1087.
Voorhees, Irving Wilson: A Volunteer's reasons, 340; prophylactic vaccines in influenza, 820.

W

Wakefield, Homer, Biological factors of the war psychoneuroses and complementary phenomena, 794; the physical basis of war shock, a plea for the more physical concept and basis of treatment of the mental and incapacity delinquency of victims
